

TROPICAL DISEASES BULLETIN

ISSUED UNDER THE DIREC-
TION OF THE HONORARY
MANAGING COMMITTEE

VOL. 43 (Nos.
JANUARY—DECEMBER)

London:
BUREAU OF HYGIENE AND TROPICAL DISEASES
Keppel Street, W C 1

1946.

HONORARY MANAGING COMMITTEE

APPOINTED BY THE SECRETARY OF STATE FOR THE COLONIES.

Chairman W H Kauntze, C.M.G., M.B.E. M.D., D.P.H., F.R.C.P.

(Chief Medical Adviser to the Secretary of State for the Colonies)

Wm Horner Andrews, D.Sc. M.R.C.V.S.

Lieut-General Sir James Bennett Hance, A.C.J.E. O.B.E., M.D., F.R.C.S.Ed. K.H.S.
I.M.S. (ret'd)

Professor Patrick A. Buxton, C.M.G. M.A. M.R.C.S. L.R.C.P., D.T.M. & H., F.R.S.
(representing the Royal Society)

Sir Wilson Jamieson, K.C.B. LL.D. M.D. F.R.C.P., K.H.P.
(representing the Ministry of Health)

Professor J M Mackintosh, M.D. F.R.C.P. D.P.H.

Sir Philip Manson-Bahr C.M.G. D.S.O. M.D. F.R.C.P., D.T.M. & H.

Sir Edward Mellanby A.C.B., M.D. F.R.C.P., F.R.S.
(representing the Medical Research Council)

E R A. Merewether M.D. F.R.C.P. F.R.S.E.

Major G S Parkinson, C.B.E., D.S.O. M.R.C.S. L.R.C.P., D.P.H. R.A.M.C. (ret'd)

J B. Sedgemoorham, C.M.G., M.A. *(of the Colonial Office)*

Secretary J K. Croer *(of the Colonial Office)*

STAFF OF THE BUREAU

Director Charles Wilcocke, M.D. M.R.C.P. D.T.M. & H.

Assistant Director H. J O'D Burke-Gaffney O.B.E. M.D.

Secretary R. L. Sheppard.

SUMMARY OF RECENT ABSTRACTS *

I CHOLERA

Epidemiology

ROGERS (p 282) has collected additional data from India which support the contention he has previously made that epidemics of cholera can be forecast by close observation of the south west monsoon rains of July to October. The danger of spread of cholera by pilgrims returning from a fair can be foreseen from the climatic data at the time and a knowledge that cholera is present in the areas through which the pilgrims have to travel.

Rogers concludes that as the climatic conditions are beyond human control the only means of prevention is by protective vaccination. In the discussion which followed the reading of Rogers's paper a speaker expressed doubt as to the value of vaccination in previous years but thought that the vaccine now available is probably better than that previously used. Cholera however is amenable to improvements in environmental domestic and personal sanitation.

In discussing the epidemiology of cholera in the Punjab YACOB (p 119) notes that the most recent fair held at Thanesar in 1941 passed off without a single case although it was attended by 500 000 pilgrims. This appears to be evidence of the efficiency of the Punjab health organization but the author seems to think that for other pilgrim centres protective inoculation of all pilgrims is the only means that can be expected to control the epidemics.

In the Kunming epidemic of 1942 93 per cent. of the vibrio strains isolated were of Inaba type 7 per cent. of Ogawa type (TANG *et al* p 120).

Actiology

In a detailed study of the growth conditions of *V. cholerae* LINTON and JENNINGS (pp 377-78) describe a simple casein digest medium to which certain salts and glucose are added and through which air (with a proportion of CO₂) is continuously bubbled. In this medium (for details of which the original abstract should be consulted) when the concentration of glucose is at the optimum (1 per cent.) the vibrios grow well to yield a five-fold increase over previous methods and as the pH is regulated by the aeration are not destroyed by the acid formed as a result of fermentation of glucose. Cultures in this

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 42. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

MOORE L. D. Incidence of Malaria among Troops in Liberia. *J. National Malaria Soc.* Tallahassee Fla. 1945 June v 4 No 2 109-13

The first contingent of U.S. troops arrived in Liberia in June 1942. Coloured troops outnumbered white by five to one. They were stationed in a highly malarious area. *Anopheles gambiae* was very prevalent. Between 80 and 90 per cent. of the indigenous infants harboured parasites, all *Plasmodium falciparum* and half of these infants harboured gametocytes. The first echelon was replaced by a second in March 1943 when the ratio of black to white troops decreased to three to one.

The first echelon was given suppressive quinine for the first five months of their stay between 50 and 75 per cent. took it regularly 40 grains a week. The incidence of malaria was 38.8 per cent. initial attacks 16.0 per cent. subsequent attacks a total of 54.8 per cent. attacks of malaria during a period of 8 months.

The second echelon lived under much better sanitary conditions but received no suppressive treatment for the first four months after arrival. They had much higher malaria rates. For a six month period the initial attack rate was 86.3 per cent. subsequent attacks 58.1 per cent. or a total malaria attack rate of 144.4 per cent.

DAS GUPTA, B. M. & SIDDONS, L. B. The Parasitology of Malaria among Destitutes in Calcutta during and after the Bengal Famine of 1943. *Indian Med. Gaz.* 1945 Mar v 80 No. 3 160-64 4 figs.

During the disastrous famine in Bengal in 1943 large numbers of destitute persons found their way to Calcutta mainly from the neighbouring districts 24 Parganas Hooghly and Midnapur. Between September 1943 and December 1944 the blood of 14,862 of these destitutes was examined. Malaria parasites were found in 4,920 (33.1 per cent.). The maximum incidences occurred in December 1943 44.0 per cent. and in November 1944 51.7 per cent. *P. falciparum* was responsible for 48.8 per cent. of the infections *P. vivax* 49.7 and *P. malariae* for only 1.4 per cent. This incidence of *P. malariae* infections is unusually low for Bengal it usually amounts to 12 per cent. or more. *P. vivax* on the other hand was more in evidence than is usual in Bengal. The minimum malaria incidence was in June two months later than normal. The *P. vivax* curve was unusual it rose steadily from November 1943 to August 1944 4 or 5 months later than the normal peak. The *P. falciparum* curve corresponded closely to that of total malaria. The undue prevalence of *P. vivax* may have been due in part to more frequent relapses than normally occur among the indigenous population malnutrition and inadequate treatment occasioned by the shortage of antimalarial drugs may have been responsible for this.

BRUMPT E. Anophélisme sans paludisme et régression spontanée du paludisme [Anophelism without Malaria and Spontaneous Regression of Malaria.] *Ann. Parasit. Humains et Comparée.* 1944-45 v 20 No 1-2, 67-91 [Numerous refs.]

This interesting dissertation is concerned with the large amount of work that has been done to explain the phenomena of anophelism without malaria and the spontaneous disappearance or diminution of malaria incidence more especially in temperate areas of Europe. A critical study of this kind does not lend itself to summary but some of its conclusions can be briefly stated.

Malaria in certain areas of Europe has often disappeared without any material alteration of conditions of housing of agricultural methods of conditions of

life generally and in spite of the persistence of numerous anophelines. In other areas malaria has disappeared as a result of a change in agricultural methods the elimination of saline surface water and the diminution of mosquito breeding places. Such methods have failed in other places where certain species of *Anopheles* or biotypes (*labranchiae elutus*) have been present. In places where malaria has disappeared and in which the abundant *A. maculipennis* present are biotypes that are but little attracted by man the regression has often begun by a diminution in the number of gamete carriers in part attributable to the use of quinine. In some such places malaria has reappeared when fresh gamete carriers have been introduced in the population. Numerous cases of locally acquired malaria in areas which had been long free from the malaria which formerly afflicted them have been reported in France and else where during the two great wars some in the neighbourhood of prisoner of war camps.

YOUNG M D STUBBS T H MOORE J A EHRLMAN F C HARDMAN N F
ELLIS J M & BURGESS R W Studies on Imported Malarias 1 Ability
of Domestic Mosquitoes to transmit *vivax* Malaria of Foreign Origin J
National Malaria Soc Tallahassee Fla. 1945 June v 4 No 2, 127-31

In Columbia S C San Francisco and Longview Texas special laboratories have been collaborating in an experiment to determine the capacity of American vector species (*Anopheles quadrimaculatus* Say and *Anopheles maculipennis freeborni* Aitken) to transmit strains of *P. vivax* imported from overseas.

One hundred and sixty lots of mosquitoes were fed on 151 patients suffering from relapsing *P. vivax* malaria. The probable origin of the infections studied was Guadalcanal 96 New Guinea 33 other South Pacific areas 7 Mediterranean area 18 (Africa 9 Europe 9) and Trinidad 6. The percentage of lots infected according to origin of infection was Pacific area 68 Mediterranean area 67 South America 67. Among the infected lots the total number of infected *A. quadrimaculatus* was 959 out of 2,489 dissected or 38.5 per cent. Infected *A. m. freeborni* numbered 1,358 out of 2,581 dissected or 52.6 per cent.

Infected mosquitoes were applied to neurosyphilitic patients. From 32 imported malaria cases transmission to 59 white patients was attempted. 21 of the strains produced infections in 43 patients.

The conclusion is that imported strains of *P. vivax* malaria can be spread by local species of *Anopheles* in the United States just as readily as indigenous strains of malaria.

Norman White

CHWATT L J The Morphology of the Pharyngeal Armature in *Anopheles gambiae* and *Anopheles gambiae* var *melas* from Southern Nigeria. *Ann Trop Med & Parasit* 1945 Oct. 10 v 39 No 2 124-8 3 figs. [12 refs.]

Attempts to separate *Anopheles gambiae* type form from its variety *melas* (raised to specific rank by RIBBANDS in 1944) (this *Bulletin* 1945 v 42 3) are still a matter of considerable uncertainty. Of all the characters and methods of differentiation so far tested the least unsatisfactory is based on the structure of the egg.

Material from Lagos identified in this way as containing thirty five *A. gambiae* and twenty five *A. gambiae* var *melas* was prepared for microscopic examination of the bucco-pharyngeal armatures. Comparison showed that there are no determinable and consistent differences between the two forms and that individual variations are extremely small. A full description of the bucco-pharyngeal armature of *A. gambiae* is given and illustrated. [See also this *Bulletin* 1945 v 42, 860]

STONE A. Some Relationships of *Anopheles lungae* Belkin and Schlosser (Diptera: Culicidae). *J. Wash. Acad. Sci.* 1944 Aug 15 v 34 No. 8 273

Anopheles lungae Belkin and Schlosser is closely related to *A. tessellatus* Theo. and to *A. longirostris* Brug. Characters are given for separating the females. The larva of *A. lungae* is distinguishable from that of *A. tessellatus* but as yet no differences from that of *A. longirostris* have been observed.

The three species have characters in common which distinguish their adults and larvae from those of *A. punctulatus* Dön., *A. annulipes* Walker, *A. farauti* Lav. and *A. amictus* Edw.

A. tessellatus occurs from India to Hong Kong, in the Netherlands Indies and the Philippines, with a few records from the Moluccas and a doubtful one from New Guinea. *A. longirostris* has been taken from New Guinea and New Ireland. *A. lungae* is confined to the Solomons. The distribution of these three species is not known to overlap.

H. S. Lenson

OWEN W. B. A New Anopheline from the Solomon Islands with Notes on its Biology. *J. Parasitology* 1945 Aug v 31 No. 4 236-40 2 pls.

The female, male and larva (but not the egg or the pupa) of a new species *Anopheles kolensis* are described from material collected along the north coast of Guadalcanal in the Solomon Islands. The description is based on fifty caught females and their 500 progeny (300 females and 200 males) and several hundred other specimens. Of 500 females caught in tents over several weeks 90 per cent. were *kolensis*, 5.8 per cent. were *farauti* and 4.2 per cent. were *punctulatus*. During the same period 10 per cent. of the total anopheline larvae collected were *kolensis*, indicating that the new species has a greater preference for entering human habitations than the other anophelines, and thus is of primary importance in disease transmission.

Morphologically *kolensis* lies between *A. punctulatus* and *A. farauti* and the distinguishing characteristics are discussed. Adult and larval features of the new species are illustrated.

[Because of the obscurity of the taxonomic relationships of the *punctulatus* group it remains to be seen whether *kolensis* and *moluccensis* are identical. In this important complex group the following "species" have now been *A. punctulatus moluccensis farauti kolensis*]

H. S. Lenson.

BELKIN J. \ KNIGHT K. L. & ROZEBOOM L. E. Anopheline Mosquitoes of the Solomon Islands and New Hebrides. *J. Parasitology* 1945 Aug v 31 No. 4 241-63 27 figs. on 3 pls.

The anophelines dealt with in this paper are *Bironella* (*Brugella*) *hollandi* Taylor, *Anopheles* (*Maccomysia*) *solomonis* n. sp., *A.* (*M.*) *lungae* Belkin and Schlosser, *A.* (*M.*) *punctulatus* Doenitz, *A.* (*M.*) *farauti* Laveran and *A.* (*M.*) *kolensis* Owen.

Keys to the identification of females, males, pupae and fourth-stage larvae are given, but the authors consider that the key to the males is not entirely satisfactory. Detailed descriptions follow the keys, though the only egg described is that of *B. hollandi*. Taxonomy, distribution and biology of each species are discussed.

The new species *A. solomonis* appears to be closely related to *A. lungae*. Both occur in Guadalcanal; the latter occurs also in New Georgia and Bougainville and the former (doubtfully) in New Georgia. Larvae and pupae of both species have the habit of working their way out of the water on to leaves and banks, and they cannot be distinguished in the field. Little is known of the

habits of *A. solomonis* adults but *A. lungae* rests by day on tree trunks in swampy jungle two or three hundreds have been collected from one tree. They do not attempt to bite when disturbed but return immediately to their resting place. Activity begins about 6.30 p.m. and in an hour all adults are on the wing. About 6.30 a.m. they have all settled down again. In the Lunga area of Guadalcanal *A. lungae* formed about 2 per cent of the total night catches for over a year the remainder being *A. farauti*. No *A. lungae* were taken in native villages and other evidence confirms that this species is not attracted to man.

A. punctulatus, *A. farauti*, *A. koliensis* and *A. moluccensis* form a closely related series in the group *Neomyzomyia* though the exact relationship of *moluccensis* to *farauti* and *koliensis* is not clear.

[In 1944 KNIGHT and FARNER (this *Bulletin* 1945 v. 42 688) produced evidence to show that the form of *A. punctulatus* Doen known as *moluccensis* Sw and Sw in the New Hebrides should be designated *A. punctulatus farauti* Lav. It was the only form seen there. Whether *moluccensis* and *farauti* are identical or not they were unable to say but expected that this would prove to be the case. LEVER (this *Bulletin* 1945 v. 42 778) also refers to the paper by LAFERAN published in 1902 and considers that the chief vector of malaria in Melanesia hitherto known as *A. (M.) punctulatus* Dön. *moluccensis* Sw and Sw must now be referred to as *A. (M.) punctulatus* Dön. *farauti* Lav.]

The present authors prefer to regard *A. punctulatus*, *A. farauti* and *A. koliensis* as species and not as subspecies of *A. punctulatus* because they can distinguish them in the adult, pupal and larval stages. They also regard *A. farauti* Laveran 1902 as the *A. punctulatus* of Buxton and Hopkins 1927, Paine and Edwards 1929 and Senevet 1931.

In the Solomons *A. punctulatus*, *A. farauti* and *A. koliensis* all occur on Guadalcanal. *A. punctulatus* and *A. farauti* both occur on Bougainville. *A. farauti* occurs in other islands of the Solomons group and also in several islands of the New Hebrides.

A. punctulatus is not so common as the other two species and though it feeds readily in captivity does not appear to attack man often in nature in Guadalcanal. *A. farauti* is the commonest species and formed 98 per cent of the anophelines taken in routine night catches in north west Guadalcanal during a period of over a year. Its normal feeding time is from dusk to dawn, but it will attack man in the daytime in shaded places. It is the principal anopheline attacking man except in the Koli area of Guadalcanal where its place is taken by the strongly anthropophilic *A. koliensis*. H. S. Leeson

LEVI-CASTILLO R. *Anopheles pseudopunctipennis* in the Los Chillos Valley of Ecuador. *J. Econom. Entom.* 1945 June v. 38 No. 3 385-8 3 figs.

ZUKEL, J. W. Marking *Anopheles* Mosquitoes with Fluorescent Compounds. *Science* 1945 Aug 10 157

Anthracene, rhodamine B and fluorescein have been used for marking *Anopheles maculatus*; they produce blue, red and green fluorescent colours respectively which can be seen under ultraviolet light. Anthracene can be used either as an aerosol or as a dust mixed with gum arabic. Exposure of the mosquitoes to an aerosol concentration of 10 mgm. per litre of air produces a homogeneous deposit of particles (average size 6.7 microns) on them which is apparently harmless. For use as a dust anthracene 1 part and gum arabic 2 parts are mixed in water, the mixture evaporated to dryness and ground to a powder, the mosquitoes are dusted with the powder and then placed in an atmosphere of saturated humidity for 15 minutes. The gum arabic prevents contamination of unmarked specimens during the subsequent collection.

Rhodamine B and water-soluble fluorescein are used as dyes made in the same way in the proportion of 10 mgm. of dye to 3 gm. of gum arabic.

Large numbers of mosquitoes (or other insects) can easily be marked and the identification of the marked specimens in the collections examined under ultraviolet light is rapid.

SHUTE P. G. Clinical Observations on Malaria. *Post-Graduate Med J* 1945 Aug v 21 No 238 253-61 10 charts.

An exceptionally clear and succinct account of the clinical features of the different forms of malaria, which deserves to be read by every medical man in Britain, since malaria is likely to be common in returned soldiers. A student of tropical medicine could well base his future reading on this paper which obviously embodies the author's wide and careful personal observations.

Charles Wilcocks.

RAPER A. B. WILSON Margaret E. & WILSON D. B. Dividing Forms of *Plasmodium falciparum* in the Peripheral Blood of Africans. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1945 Mar v 38 No. 4 291-5

Three cases of malignant tertian malaria are described in African natives in which dividing forms and mature schizonts appeared in the peripheral blood without there being any indication that the infection was running a particularly severe course. In two cases the patients were semi-immune in that they came from districts where malaria transmission takes place for a short period each year. Both these cases might have become seriously ill if treatment had not been carried out. The treatment however was of moderate intensity and this sufficed to bring about a clinical cure. The third case was in a fully immune individual. No treatment was given and the patient never became dangerously ill. The temperature dropped to normal on the fifth day, all parasites disappearing from the blood by the seventh day. In this case the patient had been absent from his home for two years, during which he was exposed to little if any infection. Exposure to a strain of *Plasmodium falciparum* different from the one to which he had been accustomed then took place. The dividing forms and schizonts of *P. falciparum* in these three cases were of the usual type. It is suggested that there may be a race or strain of the parasite in which peripheral schizogony occurs, or that a reticulo-endothelial system overloaded from any cause may allow schizonts to overflow into the general circulation without the grave complications usually associated with their occurrence.

PROKOFENKO L. I. [Parasite Carriage and Duration of Malignant Tertian Malaria in Middle Asia.] *Med. Parasit. & Parasitic Dis.* Moscow 1945 v 14 No 1 45-63 1 fig. [In Russian.]

An account is given of epidemiological and parasitological observations on malaria made by the author between 1942 and 1944 in three collective estates of Uzbekistan (Middle Asia) where severe outbreaks affecting almost 100 per cent. of the population, occurred in 1942.

In February 1943 it was found that, as the result of the epidemic, 10 per cent. of the population were extremely debilitated and anaemic, with protein-deficiency oedema of the face and extremities, while more than 3 per cent. had an enlarged thyroid. The spleen rate was from 19.5 to 24.5 while the parasite rate varied from 40.4 to 59.3. The predominant form of malaria was malignant tertian (383 in 1 094 persons examined or 35 per cent.) with a high proportion

of mixed infections of this and benign tertian while the number of quartan cases was negligible. Between May and October 1942 the entire population of the estates underwent several courses of curative treatment with acrinine [mepacrine] and plasmocide [pamaquin] followed by suppressive treatment.

In addition to this a number of minor hydrotechnical improvements were carried out resulting in a considerable decrease of mosquito-breeding places. In spite of intense treatment which brought about a considerable fall in the spleen and parasite rates the percentage of persons harbouring parasites remained high (5-7 per cent. of the population in summer when the rates were lowest).

The total number of persons kept under observation was 1 143 of whom 801 showed parasites. The majority of these (61.3 to 97.7 per cent.) were symptomless carriers. Paroxysms of fever occurred only in a small minority. The author concludes that carriers represent the main sources of infection leading to epidemic outbreaks in Middle Asia. Their rôle as the reservoir is further enhanced by the fact that 93.1 per cent. of malignant tertian cases harboured gametocytes. Findings of parasites in the same individuals examined from 4 to 9 times were distributed as follows: once in 67.6 per cent. of cases of malignant tertian and in 67.5 per cent. of benign tertian; twice in 24.7 per cent. of cases of malignant tertian and in 25 per cent. of cases of benign tertian. More than 60 per cent. of the repeated findings were made in the new epidemic season and presumably represented reinfections. It was also found that the duration of the infection was longer and reinfections were more common in debilitated underfed persons than in those whose diet was normal. Estimates of the duration of malignant tertian malaria based on the data of mass observations showed that the infection usually lasted 10-12 months. *C. A. Hoare*

NORONHA A. J. Atypical Malarial Gametocytes in the Peripheral Blood. *Indian Med Gaz* 1945 June v 80 No 6 298-6 figs. on 1 pl.

LAHA P. N. Malarial Nephritis (with Two Illustrative Case Reports). *Indian Med Gaz* 1945 v 80 No 3 135-7

The author refers to recently published reports on malarial nephritis and gives detailed clinical notes of two cases. A Hindu boy aged 10 had the characteristic symptoms and signs of nephritis with ascites and oedema. The manner in which the symptoms yielded to small doses of quinine after other treatment had failed to give any alleviation affords presumptive evidence that malaria was the cause of the nephritis. In the second case the rôle of malaria as the primary cause of nephritis was not so convincingly demonstrated. A definite temporary improvement in the patient's general condition followed the administration of quinine but the urine showed no sign of this improvement and uraemic coma was responsible for death a month later. *Norman White*

YAN TIM WONG. The Measurement of Blood Oxygen in Malaria with the Use of the Oximeter. *Science* 1945 Sept. 14 278-9 1 fig.

This preliminary note deals with the determination of blood oxygen levels at the time of the paroxysm in ten white subjects undergoing malarial therapy with *P. vivax*. Millikan's oximeter (see below) was used for the purpose of giving a continuous record of the percentage oxygen saturation of haemoglobin in the blood. Coloured patients were found to be unsuitable because of the fact that their skin pigment decreased the amount of light reaching the photo-electric cells and rendered the method less sensitive. Each patient acted as his own control as similar records of oxygen saturation of the blood were made

before inoculation with malaria. The results for each patient were approximately the same before and after inoculation, but varied widely in different patients according to whether they were of an active or lethargic type. During the cold stage of the paroxysm when the patient was cyanosed, the oxygen saturation increased slightly as a result of hyperpnoea. The percentage oxygen saturation then gradually fell as the temperature rose and the extent of the fall was proportional to the severity of the paroxysm—the lowest record showed a 70 per cent. saturation. The reduction in degree of saturation was not compensated by breathing pure oxygen even when accompanied by the intravenous injection of 300–600 cc. red blood cells. During a mild paroxysm the changes in saturation recorded were very small. As the temperature fell, the degree of saturation increased and reached a normal value before the temperature. In some patients the instrument was painfully irritating, especially during the paroxysm, and small doses of codeine had to be administered.

The paper by MILLIKAN (*Rev. Sci. Instruments* 1942, v 13 434) describing the oximeter contains the following paragraph — The oxygen saturation of arterial blood in man can be measured continuously *in situ* by means of bichromatic photo-electric colorimetry of the intact fully flushed ear. The accuracy of the device as determined by gas analysis of arterial blood samples is from 3 to 8 per cent. The term "accuracy" would appear to be more correctly rendered as "error". The entire optical and photo-electric system, comprising a miniature lamp bulb, two color filters and two selenium barrier layer photo-cells, weighs 30 grammes and slips over the shell of the ear. One of the color filters transmits a wave-length band which is equally absorbed by oxy- and reduced hemoglobin, thus providing a means of measuring the amount of total hemoglobin in the optical path, independent of its degree of oxygen saturation. The other color is very differently absorbed by the two hemoglobin forms. Several direct reading forms of the instrument are discussed.

NAPIER, L. E. The Present Status of Antimalarial Drugs. *New England J. of Med.* 1945 July 12, v 233 No 2, 38–43. [15 refs.]

In an interesting paper the author describes recent additions to our knowledge regarding the use and relative value of anti-malarial drugs. The conclusions reached are stated as follows —

"Prior to 1942, atabrine was looked on as a valuable addition to the armamentarium of the physician for the cure and suppression of malaria, but its place was certainly second to that of quinine. Recent work has shown that it is probably the most valuable drug in the fight against malaria.

"Despite the fact that quinine and the other cinchona alkaloids have had to take a place below atabrine on the antimalarial priority list, recent work has in no way questioned their efficacy. On the contrary, it has confirmed previous work regarding the antimalarial activity of all the crystalline alkaloids, and more especially, that of a mixed alkaloidal preparation which in some of the poorer malarious countries may, on economic grounds, still prove to be the drug of choice for the mass of the population.

"The strict limitations of plasmochin in the treatment of malaria have long been recognized, and recent experience has merely served as a reminder of these limitations. It is, however, the only drug that acts as a true causal prophylactic or actually prevents relapses in benign tertian malaria, albeit in large and dangerous doses. These unique properties should be recognized and, in special circumstances, full advantage taken of them. Furthermore, it seems possible that by a modification of the formula of plasmochin a less toxic but equally efficacious drug may be synthesized. The discovery of such

a drug will give man a weapon with which he will be able to control malaria not only in the individual but in the community. Although it is improbable that malaria will ever be banished by the use of drugs alone with a drug possessing these properties it may be possible to control it in some communities where this was hitherto impossible and in others to do so more effectively and at lower cost than would be possible by any other means. Until however such a drug is discovered no claim for man's mastery over malaria can be made.

OLDHAM Frances K & KELSEY I E Studies on Antimalarial Drugs The Distribution of Atabrine in the Tissues of the Fowl and the Rabbit. *J Pharm & Exper Therap* 1945 Apr v 83 No 4 288-93 [10 refs]

A study was made of the concentration of mepacrine (atabrine) in the tissues of the fowl and rabbit at various periods after single or repeated intravenous doses. The two species of vertebrate behaved somewhat differently especially in that mepacrine was more rapidly eliminated from the fowl than from the rabbit. When a dose of 5 mgm mepacrine per kgm was given to rabbits intravenously the concentrations at 1 hour later were—Lung 72 mgm. per kgm kidney 66 spleen 46 adrenal 32 liver 20 brain 15 and muscle 3 mgm per kgm. When the sizes of the organs are taken into account it is seen that the liver stores the greatest amount of mepacrine. In the chick little mepacrine is stored in the lungs and with the exception of the liver all the organs store less mepacrine than those of the rabbit. Mepacrine is three times as toxic for rabbits as it is for fowls. In three rabbits which were pregnant it was found that mepacrine crosses the placenta and may become stored in the foetus. Thus when the liver of the mother contained 23 mgm. per kgm the concentration in the liver of the foetus was about 3 mgm. per kgm.

F Hawking

JAILER, J W Fluorescent Microscopic Study of the Physiological Distribution of Atabrine *Science* 1945 Sept 7 258-9

SHANNON *et al* (*J Pharm & Exper Therap* 1944 v 81 307) showed by chemical determinations that atabrine [mepacrine] is localized chiefly in the leucocytes liver spleen and kidney. The present author has used the fluorescence microscope to discover what parts of these tissues contain the drug.

The source of light was an H-4 bulb with a Corning No 5984 filter in front of it and a Corning No 3894 filter in the eyepiece of the microscope. glass lenses were used the wave-length of the transmitted fluorescence being 365 mμ.

Frozen sections from fresh or fixed (formalin) tissue were mounted in saline or 0.2 M Na_2HPO_4 (atabrine shows greatest fluorescence at pH 9.5 in aqueous solution).

Adult mice were given intraperitoneal injections of a 2 per cent. solution of atabrine hydrochloride 2 mgm. daily up to totals of 4 to 12 mgm. un.injected mice were controls. The tissue of normal mice shows a slight yellowish fluorescence diffused throughout the section and barely visible at high magnifications (440×) while the fluorescence of atabrine is yellowish-green and so much more intense that the yellowish background becomes invisible.

In the liver the fluorescence was diffusely distributed throughout the parenchymal cells there was little in the Kupffer cells and the sinusoids appeared black. In the spleen the fluorescence was chiefly seen in the Malpighian corpuscles with very little in the sinusoids. This suggests that there was little atabrine in the reticulo-endothelial cells. In the kidney most fluorescence was

seen in the convoluted tubules less in the collecting tubules, and little in the glomeruli. Other organs showed less fluorescence.

As no distinction can be made between atabrine and its degradation products by this method it is unknown whether the fluorescence was entirely given by atabrine

J. F. Corson

MARKSON J. L. & DAWSON J. Investigations in the Chemotherapy of Malaria in West Africa. IV. Report on a Case of Acute Mepacrine Poisoning. *Ann Trop Med & Parasit.* 1945 Oct. 10 v 39 No. 2, 117-18.

A European soldier aged 29 who had been taking suppressive doses of mepacrine for 16 months swallowed, in a fit of mental depression about 250 tablets (25 gm.) in one dose. He began to vomit after ten minutes and vomited 10 to 14 times and the vomiting was soon followed by diarrhoea. He then became weak and drowsy. When seen by the medical officer three hours after taking the mepacrine, he was collapsed and could just be roused. His stomach was washed out a yellow fluid being returned, and he was admitted to hospital at 11.45 p.m., about four hours after swallowing the tablets.

Conditions on admission—He was collapsed and stuporose temperature 97.8 pulse (barely perceptible) 80 respirations 22 skin cold and clammy no jaundice and the skin, mucosa and conjunctiva not very yellow cardiovascular and respiratory systems normal liver and spleen normal on physical examination. He was drowsy resented being moved, and could not answer questions pupils contracted reacted to light all tendon reflexes active abdominal reflexes present plantar reflexes flexor.

He was given 15 minims of 1/1 000 adrenaline intravenously and gradually improved his blood pressure an hour later was 150/100. An intravenous injection of 5 mgm. of riboflavin was given as a possible antidote to mepacrine, and two pints of 30 per cent. glucose saline were given in four hours by intravenous drip. By the following morning he had recovered and he had no further symptoms.

Laboratory examinations—Blood and cerebrospinal fluid were taken one hour after adrenaline had been given and before the glucose saline. Laboratory examinations gave the following results haemoglobin 14 gm. per cent erythrocytes 4,200 000 leucocytes 18 000—polymorph. 82 per cent. lymphocytes 14 per cent mononuclears 4 per cent.—packed red cell volume 42 per cent., blood urea 25 mgm. per 100 ml. blood sugar 90 mgm. per 100 ml. plasma bilirubin 0.5 mgm. per 100 ml., plasma mepacrine 908γ per litre. The cerebrospinal fluid contained no mepacrine. The urine contained no albumin bile sugar or acetone.

The plasma mepacrine was 183μ per litre on the third day and 90μ per litre on the fifth day the total urinary mepacrine excreted in 24 hours was 2.7 mgm. on the third day and 1.2 mgm. on the fifth day.

Obviously much mepacrine was absorbed and the quick recovery of the patient shows the low toxicity of the drug

FEDOTOV P. I. On the Antirelapse Treatment of Benign Tertian Malaria. *Med Parasit. & Parasitic Dis* Moscow 1944 v 13 No 6 54-7 [In Russian]

The author reports satisfactory results of anti-relapse treatment of B T malaria consisting of a minimum of three courses each in three cycles of 5, 3 and 3 days with intervals of 10 days between the cycles and of about one month between the courses. The daily doses are as follows. First course—0.3 gm. acriflavine [mepacrine] second and third courses—0.2 gm. acriflavine + 0.04 plasmocide [pamaquin]. In a group of patients treated according to this

scheme only 3.5 per cent relapsed as compared with 25 per cent. and 15.6 per cent. who had one and two courses of treatment respectively. In untreated control groups relapses occurred in from 25.8 to 98.6 per cent.

PODLESKER A. El cloruro de calcio en el tratamiento de las esplenomegalias palúdicas [Calcium Chloride in the Treatment of Malarial Splenomegaly] *An Policlín Enf Infecciosas del C A Videla Hospital F J Muñiz*. Buenos Aires. 1942-44 No 4 164-210 15 graphs & 3 figs [28 refs.] English summary (9 lines)

Clinical notes and haematological studies of a series of patients suffering from chronic malaria with enlargement of the spleen demonstrate the value of chloride of calcium in the treatment of the condition. An intravenous injection of 10 cc. of a 10 per cent. solution of calcium chloride is given on each of five successive days. The injections are given slowly. There is an almost immediate response by the contraction of the enlarged spleen and an amelioration of the associated symptoms. Malarial parasites that have harboured in the spleen are discharged into the peripheral blood stream and so rendered vulnerable to antimalarial drugs.

The claims advanced for this method of treatment are similar to those put forward by advocates of Ascoli's method. [See also this *Bulletin* 1943 v 40 13]

ANANIAN S A CHUBKOVA A I AZIZIAN A A & KOCHARIAN A A [Intermittent Irrigation of Rice Fields as a Prophylactic and Agrotechnical Measure for Malaria Control in Armenian SSR.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 1 36-45 3 figs. [In Russian.]

The authors describe the results of experiments designed to determine the best method of intermittent irrigation of rice fields as a measure for the control of mosquito breeding. The experimental fields situated in the Armenian republic (Caucasus) were divided into a number of plots some of which served as controls and were irrigated continuously while in others periods of flooding lasting 8-12 days alternated with periods of drying lasting 4, 5 or 6 days. It was found that drying the field 4 days is not long enough to destroy the mosquito larvae. The most satisfactory method is to dry the field for 5 days and then flood it for 8 days. This results in 0.3 per cent mosquito production as compared with that in control plots. Prolongation of the period of irrigation is undesirable since it enables the mosquitoes to complete their development. Though the method of intermittent irrigation somewhat lowers the output of rice it results in an economy of 32.8 per cent of water consumption which can be used for irrigating additional plots under rice.

PARKER W V & JOHNSON H A. A Universal Type Concrete Slab for Precast Ditch Linings. *Pub Health Rep* Wash 1945 May 25 v 60 No 21 582-7 14 text figs. & 2 figs on 2 pls.

The concrete slab that has proved useful in the lining of ditches of various sectional shapes measures 12 by 24 by 2 inches. It is made with a 1:2:4

mixture of cement sand and $3/8$ inch graded gravel mixture. All four edges of the slab are of the tongue-and-groove type. On the long sides of the slab the tongue on one edge and the groove on the other are formed on edges which are at an angle of $67\frac{1}{2}^\circ$ with the slab surface. The end tongues and grooves are formed on edge surfaces that are at a 90° angle with the slab surface. Figures

FIG 11

FIG 12

Details of the joint between concrete slabs lead to make a 135° angle (fig 11) or a 180° angle (fig 12)

Reproduced from *Public Health Reports* Washington]

depict the various forms of ditch lining that are possible with this universal slab. The form of joint between the slabs delays the penetration of vegetation through the joints. Details of construction and of ditch lining are clearly described and well illustrated.

PRICE M. M. & LYMAN F. E. Second Report on the Control of *Anopheles quadrimaculatus* Say in the Water-Chestnut Areas of the Potomac River 1944. *Pub Health Rep* Wash. 1945 Aug 24 v 60 No. 34 983-94 2 figs.

The control of *A. quadrimaculatus* breeding in the Potomac River where water-chestnut provides very favourable conditions for such breeding was successfully effected in 1943 by airplane dusting with Paris green [this *Bulletin* 1944 v 41 1007]. The presence of numerous malaria carriers in the military forces at Fort Belvoir and the Quantico Marine Barracks during 1944 made a continuation of effective control still more important. The amount of air plane dusting in 1944 was greatly reduced by extensive cutting of the water chestnut which was begun in May. Early cutting prevents reseedling for growth the following year. Once cut the freed plants tend to aggregate into floating mats which are favourable to mosquito breeding until the plants are washed up on shore or swept out into the river. Such temporary breeding was controlled by dusting from boats. Airplane dusting in 1944 was necessary only in the neighbourhood of two of the six military establishments Fort Belvoir and the Quantico Marine Barracks. Only 7 610 acres were dusted in 1944 as compared with 32,538 acres in the previous year. The control was effective. For all six military establishments the mean number of large larvae per 100 dips was 0.52 and the average number of adult female *A. quadrimaculatus* per resting station per observation was 0.6, a comparable figure to that of the previous year when much more extensive airplane dusting was done.

Norman White

BRACKETT S & HUGHES Carrie O Chilling as a means of retaining the Viability of the Sporozoites of *Plasmodium gallinaceum* *J Parasitology* 1945 Aug v 31 No 4 288-9

In experiments in which chicks are infected by inoculation of sporozoites of *Plasmodium gallinaceum* it is important to get as much uniformity as possible in the infections produced. When chicks are exposed to the bites of infective *Aedes aegypti* mosquitoes only 85 per cent. of them become infected and when COVNEY *et al* [this *Bulletin* 1945 v 42 865] inoculated infected salivary glands subcutaneously into 200 chicks only 97.5 per cent became infected. For many purposes e.g. drug testing there should be no uninfected birds. The injection of pooled sporozoite suspensions has always in the authors experience and in that of others produced infection.

It is also necessary to have uniformity in the character of the infections. When kept at room temperature the viability of the sporozoites decreases during the hour needed to inoculate intravenously 200 to 300 chickens as is shown by the differences in parasitaemia on the eighth day of infection. The authors colleague Dr WALETZ suggested that the ground up mosquito material should be chilled as soon as possible and kept in an ice bath during the inoculations. This resulted in more uniform infections. The sparing effect of low temperature was also shown by the increased virulence of the chilled preparations as measured by the degree of parasitaemia produced. Oöcyst counts showed that this could not be due to more intense infections in the mosquitoes. Even as short an exposure as 15 minutes to room temperature probably causes marked injury to sporozoites. *J F Corson*

MARSHALL P B The Absorption of Sulphonamides in the Chick and the Canary, and its Relationship to Antimalarial Activity *J Pharm & Exper Therap* 1945 May v 84 No 1 1-11 [12 refs.]

A study was made of sulphanilamide and eleven derivatives to measure their rate of absorption from the gut and their concentrations in whole blood and in red cells of chicks and of canaries. The drugs are absorbed more quickly and excreted from the blood more quickly in canaries than in chicks. The concentration in the red cells is usually higher in the canary than in the chick. The drugs showed pronounced activity against *Plasmodium gallinaceum* in chicks but they were mostly inactive against *P. cathemerium* in canaries. A blood concentration of 10 mgm sulphadiazine per 100 cc was very active against *P. gallinaceum* to suppress infections of *P. cathemerium* blood concentrations of 60-100 mgm per 100 cc were needed. Generally speaking the degree of antimalarial activity of these compounds in chicks can be correlated with the height of the blood concentration curves. *F Hawking*

BLACKWATER FEVER

JOURNE H. Le rein dans la fièvre bilieuse hémoglobinoïdique. Etude clinique. Conceptions hystophysiologiques et indications thérapeutiques. [The Kidney in Blackwater Fever] *Méd Trop* Marseilles 1944 May-June-July-Aug v 4 No 3 225-35

This is a review of the renal signs and symptoms pathology and treatment of blackwater fever. The author considers that the theory of blockage of the renal tubules does not explain the diversity of clinical and biological symptoms which accompany anuria and its development. He asks for instance

how the abrupt onset of anuria can be explained by obstruction of the tubules, unless there develops a sudden simultaneous complete obstruction. He considers the reversibility of the condition an argument against a purely mechanical explanation of the anuria. He points out that the urine often clears of haemoglobin before the onset of anuria suggesting that most of the haemoglobin is already excreted, and that the urine passed in the early stages of recovery from anuria does not contain the cellular and blood debris which might be expected to appear as the result of sudden clearance of obstruction in all the uriniferous tubules. He rightly emphasizes the loss of concentrating power in the post-anuric phase, and suggests that in recovery there is a sudden restoration of (glomerular) filtration in the kidney followed by a slower recovery of the damaged tubules. There is a brief second hand account of the histological appearances of the kidneys, in which the similarity between the lesions of blackwater fever crush injury and incompatible transfusion is noted.

No biochemical investigations of cases other than estimations of urea N have been carried out by the author but he suggests on the analogy of "transfusion nephritis" that there is probably a reduction in plasma chloride and alkali reserve. On these grounds he recommends alkali administration.

The author's main conclusion in this discursive paper is that the cause of anuria in blackwater fever is not yet decided and that precipitation of haemoglobin products may play a part but is not the whole explanation.

TRYPANOSOMIASIS.

FRIDGES R. N. T. W. A Sexual Reproduction Cycle of *Trypanosoma congolense* Broden. [Correspondence.] *Nature* 1945 Sept. 29 390-91

The author describes what he saw through the microscope in fresh preparations of a mixture of a drop of mouse blood heavily infected with *Trypanosoma congolense* and a drop of 0.3 per cent. solution of sodium chloride. He states that the addition of the salt solution to the blood caused sexually mature trypanosomes quickly to become micro- and macro-gametes and conjugate within ten minutes.

The macrogametes were 13-18 μ long, with somewhat anteriorly placed nucleus, both nucleus and cytoplasm being intensely granular except a posterior area which was clear translucent and swollen. The microgamete 6-8 μ long with posteriorly placed nucleus and the rest of the body an attenuated filament entered, posterior end first, the translucent area of the macrogamete and was absorbed. A motile zygote is formed, of trypanosome form but tapering from the posterior end. Nuclear material is next concentrated centrally or posteriorly and by contraction of other parts of the body an amorphous oocyst is formed. The oocyst nucleus may after sixty minutes have divided once. The zygote is about 20 μ in length, and oocyst about half this size."

Oocysts were also seen in skin and lung tissue. "The oocyst appears to form sporoblasts, probably eight, which divide into innumerable sporozoites. The sporozoites break away from the oocyst body and swim actively away by a kind of rolling movement."

The author intends to publish a preliminary paper in which more details will be given, and a full report later. [The question of the occurrence of

syngamy among trypanosomes is discussed in Wenyon's Protozoology 1926 pp 339-340 at that date no reliable evidence of its occurrence had been offered]

LEISHMANIASIS

HORGAN E. S & SATTI M H Penicillin in Kala Azar [Correspondence.]
Nature 1945 Sept. 8 297

Two adult patients in the Sudan with typical kala azar were treated with penicillin 20 000 units in 4 cc. normal saline intramuscularly at intervals of 3 hours to a total of 1,500 000 units. The result was complete failure no beneficial effect could be seen and the condition of one patient deteriorated. Gland and spleen smears remained positive.

The authors admit that kala azar in the Sudan is more resistant to treatment than kala azar in India but their experience gave no indication that better results could be achieved by larger doses and continuous administration

Charles Wilcocks

FULTON J D & GOODWIN T W Studies on the Estimation and Precipitation of Stilbamidine *J Pharm & Exper Therap* 1945 May v 84 No 1 34-41 1 fig [11 refs]

A spectrographic method is described for estimating stilbamidine in biological fluids for the technical details of this the original paper must be consulted. About 2 cc. of serum is required, which was obtained by pooling the blood of several mice. The method measures down to 5 μ gm. per cc. with an accuracy of ± 3 per cent at levels less than 2 μ gm. per cc. measurements cannot be made. When the maximum tolerated dose of stilbamidine is given to mice orally intravenously intraperitoneally or subcutaneously the serum concentration reaches 40 μ gm. per cc. within half an hour and then rapidly diminishes. Within 1-2 hours, only traces remain in the blood. Clearly the compound is rapidly absorbed and stored or excreted. When the minimum amounts required to cure infections of *Trypanosoma rhodesiense* are given to the mice the serum contains only traces of the drug. Contrary to what had previously been reported the authors found that absorption of stilbamidine by red blood corpuscles was non-existent or negligibly small. Stilbamidine is precipitated from the blood by many agents including some e.g. trichloroacetic acid metaphosphoric acid, which are used to remove proteins. It is also precipitated by sodium citrate

F Hasking

FULTON J D & GOODWIN T W The Effect of Light on various Aromatic Diamidines in the Solid State *J Pharm & Exper Therap* 1945 May v 84 No 1 42-5

When stilbamidine 4,4'-diamidino tolane and 4,4'-diamidino- α -methylstilbene are exposed to sunlight in the dry solid state they often become yellow. The authors found that in spite of this change there was no significant alteration in the absorption spectra, toxicity for mice or therapeutic action (tested

against *Trypanosoma rhodesiense*). Accordingly it is considered that solid specimens of stilbamidine etc. which have gone yellow after exposure to light in the tropics, can still safely be used for human treatment. When one of these yellow samples of stilbamidine is dissolved and then exposed to light it undergoes the same increase in toxicity as unexposed solids do under the same conditions.

BERBERIAN D. A. Cutaneous Leishmaniasis (Oriental Sore) VI. Treatment with Quinacrine Hydrochloride. *Arch. Dermat. & Syph.* 1945 July, 52 No 1 26-7

In 1838 it was reported by FLARER (this *Bulletin* 1939 v 36 454) that he had obtained good results in the treatment of oriental sore by infiltrating the surrounding skin with solutions of quinacrine hydrochloride (atebrin). This method of treatment in the hands of other observers gave varying results, though generally it was admitted that early lesions responded well. The author of the present paper tested the treatment in six cases of oriental sore which he had produced on the legs of volunteers by the intracutaneous inoculation in each case of 0.2 cc. of a suspension of culture of *Leishmania tropica* containing approximately 200,000 organisms. All sores were 157 days old when treatment was commenced by injecting 1 to 2 cc. of 10 per cent. solution at weekly intervals. In no case did the treatment favourably affect the course of the disease. It was found on the other hand, that intravenous injections of neostibosan hastened the healing of sores in the ulcerating stage. It was also observed that the subcutaneous injection at bi-weekly intervals of 0.1 to 0.5 cc. of a vaccine of killed culture forms of *Leishmania tropica* (3 to 5 million organisms per cc.) caused sores to ulcerate and thus favoured a rapid healing. [See also this *Bulletin* 1944 v 41 470]

FEVERS OF THE TYPHUS GROUP

UNITED STATES PUB. HEALTH SERVICE. NATIONAL INST. OF HEALTH. BULLETIN No 183. *Studies of Typhus Fever* [TOPPING & H. BENGTSON, I. A. HENDERSON, R. G. SHEPARD, C. C. SHEAR, M. J.] pp vi+110 17 graphs. 1945. Washington, D.C. Federal Security Agency U.S. Pub. Health Service

This little volume contains nine Reports dealing with part of the work carried out during the three years, 1942-44 at the Rickettsia Unit of the Division of Infectious Diseases of the National Institute of Health, U.S.A. Hitherto these papers have been distributed to only a small list of workers; the dates on which they would have been published in normal circumstances are shown in the following abstract—no changes have since been made in the texts. Some of the observations have already been incorporated in the present methods of vaccine production.

The volume, appropriately, is dedicated to the memory of one of the authors, Richard Gray HENDERSON, who died on October 20, 1944 of tsutsugamushi disease (scrub typhus) contracted while he was investigating this infection.

Studies of Typhus Fever Vaccines

(TOPPING, BENGTSON and SHEAR. March 27 1942.)

(i) Topping and Bengtson found that the Cox type of vaccine then in use did not cause a great increase in the complement fixation titres of guinea-pigs and that the immunity produced in the animals could be almost completely

broken down by challenge with virulent suspensions of rickettsiae. Other vaccines tested were Craigie's modification of the Cox vaccine Castañeda's rat lung endemic typhus vaccine and Giroud's mouse-lung epidemic typhus vaccine. The percentage of guineapigs in which standard doses of each vaccine caused a rise in the complement fixation titre to 1-64 were —With the Giroud vaccine 63 the Castañeda vaccine 30 the Craigie vaccine 26 and the Cox vaccine 9.5. In the tests of vaccinated guineapigs challenged by very large and equal doses of rickettsiae the average number of days of fever resulting from the challenge were —With the Giroud and Craigie vaccine 0.4 each the Castañeda vaccine 3.6 and the Cox vaccine 4.5. In unprotected guineapigs the average was 9.0 days.

(ii) Topping and Bengtson carried out similar tests with the Cox type vaccine precipitated by alum. When this was given in a single dose of a four times concentration the complement fixation titres were high and the challenged guineapigs had either no fever or only one day of fever. In human tests this vaccine given in two doses produced a higher complement fixation titre than the ordinary Cox vaccine.

(iii) Topping and Shear studied the antigens found in infected yolk sacs that had been treated with ether according to Craigie's method. The supernatant fluid of centrifuged yolk sac suspensions contained important antigens capable of causing positive complement fixation reactions in guineapigs strongly positive Weil-Felix responses in rabbits and immunity in guinea pigs. It was therefore thought desirable to include this soluble antigen in the preparation of vaccines [see also a paper by the same authors in this *Bulletin* 1945 v 42 457].

(iv) Bengtson found that under certain conditions the infecting agent in yolk-sac cultures passed through a Berkefeld N filter. Chick embryos inoculated with the filtrate survived 10-12 days and their yolk sacs usually contained larger numbers of rickettsiae than those inoculated with unfiltered suspensions. Other methods of increasing the yield of yolk sacs are discussed. There was a general degree of correlation between the number of rickettsiae in yolk sacs and the titre of the complement fixation reaction in immunized animals though great individual differences were observed.

A vaccine was prepared by ether treatment of homogenized yolk-sac suspensions without previous centrifugation so that the soluble antigen was retained. After removal of the ether at 37°C and slow centrifugation (1 000 r.p.m. for 10 minutes) the suspension was precipitated by alum.

Epidemic Typhus Demonstration of a Substance Lethal for Mice in the Yolk Sacs of Eggs Infected with R. prowazeki

(BENGTSON TOPPING and HENDERSON July 31 1942.)

A toxic substance present in rich yolk-sac cultures of *R. prowazeki* killed mice within one to six hours when injected intravenously in sufficient doses which for different cultures were 100 per cent. apart diminishing from 0.5 cc. of a 5 per cent. suspension of yolk sac.

This toxin was destroyed by (1) Heating for half an hour at 60°C (2) formalin at a concentration of 0.375 per cent. (3) treatment with ether for 30 minutes. The substance appeared to be closely associated with the rickettsial bodies because it was absent from the supernatant fluid after high-speed centrifugation and from the filtrate after passage through a Berkefeld N filter. The toxin was neutralized by immune serum.

The number of minimum lethal doses in 1.0 gm. yolk sac was 40-320 in yolk sacs containing very numerous rickettsiae and less than 40 in those containing few rickettsiae.

Notes on the Preparation of Epidemic Typhus Vaccine

(TOPPING August 10 1942)

Details are given of a method of preparing the vaccine which was adopted after further study. In outline the process was as follows—A 30 per cent. suspension of yolk sacs was homogenized in saline containing 0.75 per cent. phenol and 0.3 per cent. formalin. This was kept 24 hours in a cold room and then made into a 10 per cent. suspension by the addition of saline. To it one and-a-half volumes of ether were added, and it was shaken moderately for one or two minutes in a V-shaped funnel. After keeping for 24 hours in a cold room the aqueous phase was drawn off and freed from ether *in vacuo*. Alum precipitation was still under trial but was not recommended for general use.

Notes on the Mouse Test with Typhus Vaccine

(TOPPING August 10 1942)

The power of sera of vaccinated guinea-pigs to neutralize the toxic substance contained in yolk-sac cultures was estimated. Full details are given of the technique.

Epidemic Typhus Vaccine Preparation of Seed Virus for the Inoculation of Eggs and of Lethal Material for the Neutralization Test in Mice

(BENGTSON February 19 1943)

The richest vaccines were obtained from yolk sacs infected with dilutions of 1-10,000 of yolk sacs very rich in rickettsiae. The best harvests were obtained from the sacs of chicks still surviving after 6-10 days. More uniform vaccines were obtained by pooling yolk sacs collected over a period of several days and keeping them frozen at a low temperature till used. The longest survival times of inoculated chick embryos and often the richest vaccines were obtained from yolk sacs inoculated with a 10 per cent. saline suspension of yolk sac which had been passed through a Berkefeld V filter. Sometimes, however, the filtrate was non-infective. For mouse-neutralization tests very rich yolk-sac suspensions in sterile milk were used.

Epidemic Typhus Fever Neutralization of the Toxic Substance

(HENDERSON and TOPPING March 19 1943.)

By an extensive series of experiments it was found that the mouse-neutralizing test served to measure the amount of neutralizing antibody contained in the sera of persons or animals after attacks of typhus fever and after vaccination against the disease. Very high titres were observed in convalescent patients and substantial titres often persisted for several months after attacks. In vaccinated persons the titres were much lower and they declined more rapidly yet they were considerably higher on the average than in vaccinated guinea-pigs.

The test was regarded as an important adjunct to other procedures for the investigation of typhus fever.

Epidemic Typhus Fever a Study of the Antigenicity of Various Strains of Typhus Virus.

(TOPPING BENGTSON and HENDERSON September 24 1943.)

Tests were carried out with Breuil, Colombian, and Spanish strains of epidemic typhus rickettsiae and with the Wilmington strain of endemic rickettsiae.

No significant differences were found in the vaccines prepared from the various epidemic strains but guinea pigs vaccinated with the endemic strain had little if any protection against challenge with epidemic strains. Mouse-neutralizing tests gave similar results.

These experiments showed that sharp specific differences existed between the epidemic and endemic strains.

Sera of guinea pigs inoculated with killed typhus antigens showed considerably higher titres of protection against homologous than against heterologous strains of antigen. The differences in the titres after experimental attacks were less pronounced.

Epidemic Typhus Fever Studies of Epidemic Typhus Vaccine

(TOPPING HENDERSON and BENGTSON February 18 1944)

In April 1942 320 persons were immunized some by two doses of 1.0 cc. of fluid vaccine others by equivalent doses of alum precipitated vaccine. Members of the latter group did not develop complement fixation antibody as consistently or in as high a titre as those vaccinated with equivalent doses of fluid vaccine.

Neutralizing antibodies were developed rather uniformly after vaccination with either type of vaccine and they persisted longer than the complement fixing antigens.

A booster dose of vaccine given some months after the primary vaccination caused a much higher and more persistent rise in both types of antibody than the original vaccination. The neutralizing antibodies were produced more consistently and persisted much longer than the complement fixing antibodies. The agglutination of *Proteus OX19* was not stimulated either by the primary or the booster vaccination.

Technic of a Precipitin Test for the Study of Typhus Fever

(SHEPARD and TOPPING May 19 1944)

Details are given of the methods of preparing a clear solution of antigen and a potent antiserum. Examples are given to show the applicability of the test to the measurement of antigen and antibody. The use of the test is not limited to intact organisms as is the case with agglutination tests nor to live organisms as in the mouse-neutralizing test. Only two reagents with good keeping properties are needed. For details the original paper must be consulted.

Typhus Fever Antigens of the Rickettsiae of Typhus Fever and the Changes Produced by Heat

(SHEPARD June 9 1944)

Craigie *et al* are quoted as having shown that when epidemic and murine rickettsiae are heated to 60°C the type specific, heat labile antigens are destroyed whereas the heat stable antigen common to both types is not affected (CRAIGIE *et al* 1943 Memorandum No 7 Project Med 8 National Research Council of Canada).

In the present study Shepard used the precipitin complement fixation and mouse-neutralizing tests. The sera of rabbits immunized by heated epidemic and murine rickettsiae did not give a positive precipitin reaction with unheated antigens but they did react with heated antigens. Sera of rabbits and guinea pigs immunized with heated antigen contained no neutralizing antibodies and the guinea pigs were still susceptible to challenge with virulent rickettsiae. It appeared therefore that the heat-stable antigens

were not concerned in the production of immunity they were also found to have little epidemic or endemic type-specificity and to have a broadened range of reaction with the precipitin test so that for example they gave positive reactions with sera of animals immunized against *Proteus O\19*.

From these and other observations recorded in the paper the author concludes that the cross immunity between epidemic and murine typhus is not due to the absence of specificity in the heat-stable antigens, but to a similarity of the unheated antigens.

GREIFF D & PICKERTON H Effect of Enzyme Inhibitors and Activators on the Multiplication of Typhus Rickettsiae. II. Temperature, Potassium Cyanide and Toluidin Blue. *J Exper Med* 1945 Sept 1 v 82 No 3 193-206. 16 refs.

The present study is in continuation of work already done by the authors in which they showed that penicillin and para-aminobenzoic acid (PABA) inhibited the growth of typhus rickettsiae in the yolk sac. [See this *Bulletin* 1945 v 42, 362.

In the present experiments murine rickettsiae of the 45th passage were used. The authors found that the following factors affected the growth and multiplication of rickettsiae in the endodermal cells of the yolk sacs of hens eggs —

(1) Reduction of the time of blending of the infecting suspensions from four minutes to ten seconds caused a considerable average increase in the multiplication of the rickettsiae. (2) Eggs of Wyandotte hens yielded scanty cultures as compared with eggs of White Rock hens in which growth was abundant. It was thus possible to obtain cultures of varying richness for different types of experiment. (3) Growth was much more active in eggs incubated at 37.5°C than in those incubated at 40°C. (4) Suitable doses of potassium cyanide solution introduced into the yolk sacs greatly stimulated the growth of rickettsiae presumably by depressing the metabolic activity of the cells. (5) Toluidin blue delayed the development of rickettsiae by about three days, but the inhibiting action wore off as the dye became decolorized, and repeated injections were impracticable. (6) The inhibiting action of a temperature of 40°C was neutralized by potassium cyanide but the similar action of toluidin blue was not affected, so that the mechanism of inhibition have been different. (7) The inhibiting action of PABA was not neutralized by potassium cyanide.

Several compounds related to PABA were tested but no inhibiting action was detected.

GRENOUILLEAU G L'épidémie de typhus en Algérie (1941-1942-1943). [The Epidemic of Typhus Fever in Algeria (1941, 1942, and 1943). *Arch Inst Pasteur d'Algérie* 1944 Dec v 22, No 4 353-79 4 graphs.

The incidence of louse-borne typhus in Algeria during each of the four successive seasons October to the following September was as follows — 1939-40 11,874 1940-41 55,530 1941-42, 193,352 and 1942-43 45,408. The seasonal incidence was of the usual type for example there were 306 cases in October 1941 and a steady rise reaching the peak figure of 6,106 cases in March 1942. High but gradually declining figures were recorded in April, May and June. In July a rapid fall set in, and in September the figure was 352. The author believes that all the official figures ought to be multiplied by five or six to give a true estimate of the number of cases that actually occurred.

Considerable importance is attached to the carry-over of infection by the dried faeces of infected lice and possibly of fleas though mild and inapparent attacks in children are also important. The fatality rate among the indigenous population was 22 per cent among Europeans it was 30.7 per cent ranging from 5 per cent in children of 10 years and under to 100 per cent in persons over 70.

More than 3½ million doses of Blanc's live murine vaccine were administered between December 1941 and January 1944. The Durand and Giroud killed vaccine was administered to 297 000 persons. Examples are given of the striking success that resulted in several localities from the use of the Blanc vaccine which however had the drawbacks of causing attacks of murine typhus in 5-6 per mille of the persons vaccinated and of being somewhat unreliable at times. There never was the slightest reason to suspect that murine infection was introduced into any locality as a result of the use of the vaccine. The killed vaccine of Durand and Giroud had been given to 13 medical men who subsequently contracted the disease but none of them died. There were 14 deaths among 19 non vaccinated medical men so that the life saving effect of the vaccine was clearly demonstrated. It is also stated that no death was known to have occurred among the 297 000 persons protected by this vaccine which was also completely safe. The chief drawbacks of the killed vaccine were the necessity for giving two or three doses and the short duration of the resulting immunity which was estimated to be six months against about three years in the case of the live vaccine.

LAURET is said to have already developed a murine live vaccine prepared from the brain of the white mouse and applied by scarification of the skin.

The Pasteur Institute of Algeria is producing a killed vaccine for use in a single dose of 2 cc. and specially intended for communities which are already partly immune to the disease.

In a footnote it is claimed that the measures adopted have brought the epidemic under control in conditions in which it would have been expected to persist during the first six months of 1944 only 874 cases were reported. The chief credit is given to vaccines, disinfection and disinfection on the necessary scale were found to be impracticable in the conditions that existed during the epidemic. A supply of DDT obtained from the Rockefeller Foundation was strikingly successful in the localities in which it could be employed.

MACCHIAVELLO A. & CIFUENTES O. Significación epidemiológica de los caracteres clínicos del tifo exantemático al final de una epidemia. [The Epidemiological Significance of the Clinical Features of Exanthematic Typhus Fever at the End of an Epidemic.] *Rev. Chilena de Hig. y Med. Preventiva* 1945 Mar v 7 No 1 15-33. English summary.

The authors present a critical statistical analysis of the chief clinical features of 225 cases of louse borne typhus observed between May 28th and September 2nd 1939. During this period the 1937-39 epidemic in Santiago was coming to an end and the authors conclude that at such a time the number of mild and atypical attacks tends to increase, so that cases are likely to be missed unless this matter is borne in mind.

Although the fatality rate of 24 per cent does not suggest that the disease was of a specially mild type a number of interesting points are brought out in the tables and in the text.

After a primary defervescence and clinical cure 69 of the patients had a recurrence of the fever lasting one to three days but without special symptoms and the temperature seldom rose as high as 39°C. In some severe cases the

temperature fell to normal before the signs and symptoms had completed their evolution. The termination was by crisis in 51 cases and by lysis in 75. In the others the secondary rise of temperature occurred or the termination could not be observed.

Among 182 cases the duration of the fever was 3-8 days in 3, 7-8 days in 9, 9-12 days in 73, 13-16 days in 80, and 17-24 days in 17.

The Weil-Felix titre rose to 1-160 or over in 214 of the 225 cases. Relatively low titres of 1-160 and 1-320 occurred in 75 patients of whom 14 died. In the remaining 139 patients the titres were 1-600 or 1-1 000 and among these there were only eight deaths.

Complications involving the lungs occurred in 74 cases. pneumonia occurred in 12 cases, severe bronchitis in 7, bronchopneumonia in 4, pleurisy and acute laryngitis in 2 each. There was only one case of suppurative otitis, parotitis, thrombosis or haemorrhage are not mentioned in the text or shown in the table.

John W D Megeu

FALIN L. I. [Changes in the Nervous Elements of the Skin and some other Organs in Typhus Fever] *Synll. Eksper Biol i Med* Moscow 1945 v 19 No 3 33-7 3 figs. [In Russian]

With a view to throwing light on the mechanism of the vasomotor secretory and trophic disturbances in typhus fever the author has studied the changes undergone by the terminal portions of the peripheral nervous system. Special attention was devoted to the histopathology of the nerve fibres and endings in the skin, since—like the central nervous system—this is one of the chief regions where the characteristic vascular changes occur. For comparison, a study was also made of the corresponding nervous elements in the epiglottis.

As the result of this investigation the author arrives at the following conclusions: (1) In typhus fever the elements of the peripheral nervous system of the skin and epiglottis are markedly but irregularly affected. (2) The changes undergone by the nerve fibres are usually degenerative but in some cases they are due to irritation. (3) The sensory nerve endings in the skin of the type of Meissner's and genital corpuscles (the end-bulbs of Krause in the glans penis) usually retain their normal structure but some exhibit phenomena of irritation in the form of globular thickenings (*Angel'sk nomen*) at the end of the terminal filaments. (4) In view of the relatively good preservation

the sensory nerve endings and of the thick myelinated fibres in the skin in the epiglottis it would appear that the majority of degenerated nerve fibres observed in the nerve plexuses belong to the vegetative and in particular to the sympathetic system proper.

YEOMANS, A. SKYDER J. C. & GILLIAM A. G. The Effects of Concentrated Hyperimmune Rabbit Serum in Louse Borne Typhus. *J Amer Med Ass.* 1945 Sept. 1 v 129 No 1 19-24 [Refs. in footnotes.]

Concentrated hyperimmune rabbit serum, prepared by the Lederle Laboratories was administered to 25 patients who had not been vaccinated against typhus at the Cairo Fever Hospital in a ward placed at the disposal of the U.S.A. Typhus Commission. The patients were Egyptians aged 18-48 years in whom the time of onset of the fever was clearly less than seven days. For reasons "not pertinent to this discussion" the system of alternate controls was not adopted, but 44 other cases comparable in all respects except as to the dates of onset served as controls.

Each patient was tested for sensitiveness to rabbit serum by intradermal injection of 0.1 cc. of a normal animal's serum. the response was observed

after 20 minutes. The specific serum was injected daily intravenously intramuscularly or usually by both routes. The initial dose was 1.0 cc. for each pound of body weight the later doses were 0.25 cc. for each pound of weight. Intravenous injections were given at a rate of not more than 0.5 cc per minute for the first 5 cc. and afterwards a rate of 4 cc. was never exceeded. Chills occurred in seven cases probably because of imperfectly prepared glassware. Vomiting occurred in one with a fall of 24 mm. in the systolic blood pressure. Nausea occurred in two with a fall of 16 mm. in the systolic pressure. Headache was caused or increased in 11 cases. Intramuscular injections of serum up to a maximum of 115 cc. in 24 hours were made into the buttocks. The average quantity of serum given to each patient was 186 cc. the range was 51 to 512 cc. The duration of the treatment varied from one to six days.

No death occurred among the 25 treated patients there were eight deaths among the 44 controls. The average duration of the fever in the treated subjects was 13 days in the controls it was 18½ days. The most convincing evidence of the efficacy of the treatment was the remarkable mildness of the attacks in the 10 patients whose treatment was started on the second or third day in seven of these the attacks were exceptionally mild in two it was moderately severe and in one it was severe. The fever lasted for only seven or eight days in four of these patients it lasted for 10-14 days in five and for 17 days in one. A comprehensive analysis of the chief features of the cases is presented in tabular form. Seven of the patients had serum sickness. Rickettsiae of the epidemic type were isolated from 18 of the 25 patients.

It was concluded that the serum had a favourable therapeutic effect when the treatment was started within the first three days of the illness, when started later its value could not be determined with certainty. From the data available it appeared that para-aminobenzoic acid had a more definitely favourable effect on patients who came under treatment after the third day [see this *Bulletin* 1945 v 42, 201].

The serum is available in very limited quantities and presumably it is very costly so that its use is likely to be restricted to medical or sanitary personnel over the age of 40 and it would be specially needed by patients who had not been vaccinated or who had been incompletely vaccinated.

ALLEN A. C. & SPITZ Sophie. A Comparative Study of the Pathology of Scrub Typhus (Tsumugamushi Disease) and other Rickettsial Diseases. *Amer. J. Path.* 1945 July v 21 No 4 603-81 88 figs. (14 coloured) on 18 pls. [57 refs.]

This study was carried out at the Army Institute of Pathology, Washington. The tissues investigated came from 74 cases of scrub typhus in the New Guinea area from 24 cases of epidemic typhus in Egypt and from 12 cases of Rocky Mountain spotted fever. The paper is illustrated by 86 excellent photomicrographs of which 14 are coloured. It deals almost entirely with the morbid histology of the diseases and one special object of the study was to determine whether any of the changes observed in mite-borne typhus were sufficiently characteristic and constant as to permit a histological differentiation of the various typhus fevers.

The study is of special value because of the wealth of material that was available and because this material was thoroughly investigated by a single team of highly skilled observers. [The findings however cannot be regarded as universally applicable in all respects to each of the three typhus fevers. All of these are known to show a wide range of variability in their clinical aspects so that although the morbid histology of each may conform to a single

general pattern considerable variations in the details of the pattern can be expected to occur in different outbreaks of the disease. The descriptions of the morbid histology of louse borne and mite-borne typhus by various competent observers provide clear evidence that these variations do occur. This comment does not detract from the great intrinsic value of the paper.]

In the detailed description of the eschar of scrub typhus the important part played by secondary, chiefly staphylococcal infection is clearly shown. The lesion begins as a vesicle which soon becomes a pustule associated with a strictly local thrombophlebitis and arteritis of a septic type. The rickettsial reaction is seen in the veins at some distance from the central area. It takes the form of a mononuclear infiltration of the vessel walls. Sometimes there is also swelling of the endothelial cells and occasionally non-occlusive thrombus is seen.

In the skin macules the equivalent of the "typhus nodule" is seen in the arterioles, capillaries and veins. The changes observed in these vessels "appeared to constitute an expression of intrinsic vascular usually intimal damage."

The macules of louse-borne typhus are essentially similar but the capillary thrombi, though less constantly present, are more conspicuous when they do occur and the endothelial cells are more obviously damaged. There is also a tendency to a necrotizing arteritis which is not found in scrub typhus. The macules of Rocky Mountain spotted fever and also of boutonneuse fever resemble those of louse-borne rather than of mite-borne typhus.

The vascular changes found in other parts of the body are of the same general type and the conclusion is reached that arteritis is exceedingly slight in scrub typhus in contrast with epidemic typhus and Rocky Mountain spotted fever.

The percentage incidence of some of the chief findings is shown in the following table which has been compiled from the tables and other information contained in the paper —

	Scrub Typhus	Epidemic Typhus	Rocky Mountain Fever	Remarks
Interstitial myocarditis	93	83	83	In all three groups there was a remarkable degree of preservation of the myocardial fibres.
High-grade interstitial myocarditis	49	33	25	
Interstitial pneumonia	55	35	9	
Bacterial bronchopneumonia	30	8	20	Most pronounced in scrub typhus.
Hyperplasia of lymph nodes	100	Usual	Usual	
Necrotic areas in lymph nodes	33	0	0	
Diffuse glomerulonephritis	30	78	50	
Typhus nodules in pons cerebri	33	81	?	
Typhus nodules in grey cortex	10	83	Nil	

The nodules of scrub typhus are similar in type to those of epidemic typhus the corresponding lesions in Rocky Mountain fever are microinfarcts distributed in the white matter of the cortex which was never invaded by the nodules of the other two diseases

The histological changes observed in the liver spleen pancreas adrenals and gastrointestinal tract were essentially similar in all the three groups of typhus fevers. The authors do not accept the view that the vascular atony and increased permeability observed in epidemic typhus are due to structural damage to the vessels caused directly by the presence of the rickettsiae it is pointed out that vasomotor collapse is just as striking a feature of scrub typhus as it is of epidemic typhus so that the histological findings do not support the mechanistic view. A humoral mechanism is regarded as a more likely explanation and evidence was found of damage to the cortical cells of the adrenals so that the question of adrenal insufficiency deserves consideration. Reasons are given for regarding the effects of the rickettsiae as being largely due to allergic action and reference is made to the basic clinical aetiological and in many respects immunological similarities between scrub typhus and the other rickettsial diseases. The authors classify the human rickettsioses in four groups —

I The Typhus Group (louse-borne and flea borne) with *Proteus* O\19 Weil Felix reaction

II Spotted Fever Group (tick borne) with indeterminate Weil Felix reaction

III Tsutsugamushi fever group (larval mite borne) with O\A response

IV Miscellaneous Group all with negative Weil Felix reactions. In this group are included Q fever believed to be tick borne trench fever which is louse-borne and the two problem fevers of North America Colorado and Texas tick fevers of which it is stated that proof of the rickettsial aetiology of these diseases is not yet universally accepted. *John W D Megaw*

SETTLE E B PINKERTON H & CORBETT A J A Pathologic Study of Tsutsugamushi Disease (Scrub Typhus) with Notes on Clinicopathologic Correlation. *J Lab & Clin Med* 1945 Aug 30 No 8 639-61 15 figs. [23 refs.]

The lesions occurring in tsutsugamushi disease in man and experimental animals are described in detail the paper is illustrated by 15 clear reproductions of good photomicrographs

The authors classify the human rickettsial diseases excluding the moot problem of trench fever into (1) typhus human (carried by lice) and murine (carried by fleas) (2) spotted fever (carried by ticks) (3) tsutsugamushi fever (carried by mites) and (4) Q fever (infection found in ticks but epidemiological studies are incomplete). This classification is said to be definitive on immunological grounds [The name spotted fever when divorced from the qualifying words Rocky Mountain is certainly not definitive.]

The present study is based on 55 fatal cases among American troops stationed in and near New Guinea. Special attention has been given to a comparison of the pathology of tsutsugamushi fever with that of typhus and spotted fever it is stated that in all these diseases the pathological changes are direct results of the multiplication of rickettsiae in the endothelial cells or smooth muscle cells of the blood vessels and that the organisms cause swelling and proliferation of the endothelium cellular infiltration of the vessel walls perivascular accumulation of mononuclear cells and occasionally thrombosis and haemorrhage. Epidemic typhus and spotted fever are said to have remarkably similar histopathological features except that the tendency to

The present patient was employed at a water works in Ingham, North Queensland in the course of his work he walked through drains and undergrowth near the river bank. There was no history of a bite by a tick or other arthropod.

For the first 12 days of the illness there was relatively high fever of a deeply remittent type with heavy daily sweats for the following 19 days there was a daily rise of temperature but to a lower level. The onset was with cough and blood-stained sputum so that a diagnosis of pneumonia was made. During the second week oedema of the ankles and ascites appeared, and the sweats ceased. In the third week signs of heart failure and jaundice occurred. The fever declined gradually and all the symptoms disappeared with the exception of deafness which had set in at an early stage.

The serum-agglutinating titres for *Rickettsia burneti* were 1-30 on the 28th day and 1-1 000 on the 55th day for *Proteus OXK* they were 1-80 on the 28th day and nil on the 55th day.

This was the first case confirmed as occurring in North Queensland it narrows the gap between the endemic centres of Q fever in Queensland and Montana U.S.A. by a mere 500 miles.

Bandicoots and cattle were numerous in the locality and the bandicoot tick *Haemaphysalis humerosa* has been reported by HEASLIP as occurring in North Queensland.

YELLOW FEVER.

BATES, M. & ROCA-GARCIA, M. Laboratory Studies of the Saimiri-Haemagogus Cycle of Jungle Yellow Fever *Amer J Trop Med* 1945 May v 25 No 3 203-16 2 figs. [24 refs.]

The authors have maintained a Colombian strain of yellow fever virus through five cycles in the laboratory using Saimiri monkeys as hosts and the mosquito *Haemagogus capricornis* as the vector. Details are given of the methods employed in keeping the mosquitoes in the laboratory. Wild-caught *Haemagogus* were used in all the experiments for there has been no indication of the presence of yellow fever virus in the study areas since 1940. Similarly wild-caught Saimiri monkeys were used, but only animals whose sera was previously found negative in the yellow fever protection test.

The yellow fever virus used in the transmission experiments had been recently isolated from a patient (Perez) who died of the disease contracted in the Restrepo area north of Villavicencio.

This strain produced variable results when inoculated intracerebrally into adult white mice, but 3- and 5-day-old mice were highly susceptible. It was highly virulent for Saimiri monkeys and 8 out of 10 animals infected by mosquito bite died of acute yellow fever.

The extrinsic incubation period in *Haemagogus capricornis* was found to be 22 to 24 days at 24 to 27°C and 13 to 15 days at 30°C. Only a certain percentage of the mosquitoes became infected after feeding on monkeys containing virus in the blood. The percentage infected seems to depend on the amount of virus ingested and the temperature at which the mosquitoes are kept.

The authors discuss the correlation between factors influencing the *Haemagogus* infection in the laboratory and the natural habits of the mosquito. The relatively high temperature necessary for infection is obtained by the species frequenting sunny localities in the forest canopy where the temperatures are higher than in the lower forest strata. Moreover the habits of the Saimiri monkeys in the Villavicencio area closely correspond with those of *Haemagogus*.

In view of the fact that Samurils are the commonest local primates and *Haemagogus* the most abundant Aedine mosquito one might have expected a higher incidence of yellow fever infection among them but possibly the high mortality rate may account for the relatively low rate of positive protection tests (10 out of 81) most animals not surviving the infection. *E Hindle*

WADDELL, Mary B & TAYLOR R M Studies on Cyclic Passage of Yellow Fever Virus in South American Mammals and Mosquitoes Marmosets (*Callithrix aurita*) and Cebus Monkeys (*Cebus versutus*) in combination with *Aedes aegypti* and *Haemagogus equinus* *Amer J Trop Med* 1945 May v 25 No 3 225-30 3 figs [14 refs.]

An investigation of the cyclic transmission of yellow fever by means of alternate passage through insect vector and vertebrate host with the object of helping to determine the way in which virus is maintained in certain forested regions of South America.

Three virus strains were used two Brazilian, isolated from non fatal cases of jungle yellow fever and one Colombian, isolated from a rhesus monkey infected by the bites of wild *Haemagogus* caught in the forests of Volcanes.

In the first series of experiments a marmoset *Callithrix aurita* was inoculated with virus and when the virus titre of this animal was high, *Aedes aegypti* were fed on it. These mosquitoes were kept at 26° to 28 C. for 28 days and then fed on a normal marmoset. From then on the host vector host cycles continued until the ninth cycle. No marmoset exposed to bites failed to become infected and all showed virus when first tested on the 2nd or 3rd day. 15 out of 17 died on the 4th to the 8th day. The two which recovered showed virus up to the 4th and 5th days respectively and were immune when tested on the 21st day.

A similar series was carried out with Cebus monkeys *Cebus versutus* and *Aedes aegypti* through five complete cycles. All the exposed monkeys showed circulating virus but only one out of 13 died of the infection. Those that recovered developed immunity. The virus was present in the circulation on the 3rd to the 5th days and may persist to the 7th day. The concentration was low compared with that found in the marmoset. Two cycles were also completed with the Colombian strain.

Another series was conducted with marmosets and *Haemagogus equinus*. Only three cycles were completed and four successful transfers obtained. There were also three failures but in two the incubation period in the mosquito was near the minimum and in the third failure only one mosquito was involved. In one experiment three *Haemagogus spegazzinii* a species found in regions in Brazil where jungle yellow fever is endemic were able to transmit the virus from an infected to a normal marmoset.

The results of these experiments support the view that the virus may be preserved in forested areas by passage through sylvan mosquitoes and monkeys but do not exclude the possibility that other vertebrates and arthropods may play a rôle in the epidemiology of jungle yellow fever. *E Hindle*

LAEMMERT H W Jr & DE CASTRO FERREIRA, L. The Isolation of Yellow Fever Virus from Wild-Caught Marmosets. *Amer J Trop Med* 1945 May v 25 No 3 231-2.

A record of the isolation of yellow fever virus on four occasions from wild marmosets *Callithrix penicillata* caught between June 7th and August 13th in a sharply delimited locality in the neighbourhood of Ilhéus Bahia where jungle yellow fever is endemic. All four animals were in poor physical condition

when caught and died with gross lesions suggesting yellow fever subsequently confirmed by animal experiments and histopathological examination. Later 1437 other marmosets have been obtained without any more cases of yellow fever infection being discovered.

"Yellow fever virus has never been isolated previously from naturally infected vertebrates other than man.

SMITHBURA K. C. & MAHAFFY A. F. Immunization against Yellow Fever
Studies on the Time of Development and the Duration of Induced Immunity
Amer J Trop Med 1945 May v 25 No. 3 217-23. [13 refs.]

The authors investigated the results of immunization with the attenuated yellow fever virus 17D in both monkeys and human beings.

Twelve rhesus monkeys were vaccinated subcutaneously and after intervals ranging from one to fourteen days they were tested for immunity by the inoculation of a standard dose of yellow fever virus (Asibi strain). Protective antibodies were found to develop within six or seven days, but the monkeys were completely resistant at least 24 hours before the appearance in the serum of protective bodies, i.e. within five or six days after vaccination.

Ten adult male African volunteers, each non-immune to yellow fever were similarly vaccinated, and protective antibody was found to be present in most cases by the 10th day after injection of 17D vaccine, and may be present on the 7th day. The results of post vaccination surveys of immunity in persons inoculated in Africa with 17D vaccine prepared in New York indicate that 92.2 per cent of soldiers sampled 1 to 22 months after vaccination showed protective antibodies. Ninety per cent. of civilians inoculated in Kenya gave positive protection tests 23 to 36 months after being vaccinated. More than 90 per cent of persons vaccinated in Uganda had protective sera after 3 years, and there was no decline in the incidence of immunity in the third year. Finally the percentage of children who became immune as the result of vaccination was as great as that of adults and the antibody response was equally well maintained.

Further recommendations have been made on the delimitation of yellow fever areas, to include part of N Rhodesia and changes in S America. [See *Bulletin of Hygiene* 1946 v 21 1]

PLAGUE.

ROTMAN C. M. H. Bubonic Plague in Dakar *J Roy Soc Med. Serv* 1945 July v 31 No. 3, 155-8.

Much of the interest of this account is due to the occurrence of the epidemic in the French port of Dakar. Infection of the rat population of the dockyard

seems to have come from - up-country via the railway but human bubonic plague is evidently an almost annual occurrence in Dakar itself.

Rodents along the two hundred mile coastal belt up to St. Louis and also in Senegal and in Mauretania are liable to epizootic plague. This is the animal reservoir from which Dakar becomes infected. The present considerable epidemic maintained an essentially native background. A vaccination campaign was started by the French authorities who used the living attenuated Madagascar vaccine. British and American personnel received the usual killed vaccine. Each individual vaccinated obtained a *passport sanitaire* which gave him a freedom of movement not permitted to the unvaccinated. Even those who had received killed vaccine however could not qualify for the passport without submitting to inoculation with living vaccine because the French medical authorities had no faith in the killed vaccine. A considerable reaction developed in many cases from the living vaccine in a dose of 1 cc given in the scapular region with the result that many people had tissue sloughs at the site of inoculation. It appeared that the French population and even the medical authorities took a detached view of the outbreak as they considered that plague in Dakar was a disease of natives only. When the human cases became more frequent and infected rats were no longer found, the possibility of transmission by human contact was considered. This led to the dusting of clothes of native dockyard workers with 10 per cent DDT powder to kill fleas. Treatment of plague cases at the isolation hospital was symptomatic. An interesting documentary film of the outbreak was made and this may be useful for the training of public health workers.

W F Harvey

WHEELER C. M & DOUGLAS J R Sylvatic Plague Studies. V The Determination of Vector Efficiency *J Infect Dis* 1945 July-Aug v 77 No 1 1-12 1 chart [21 refs.]

It is very desirable to have a simple standard measure of vector efficiency as a basis of comparison for different species. This vector efficiency a numerical value determined experimentally is represented by the average number of transmissions effected by a given individual flea of any species. Any normal flea may be considered to have three inherent potentials (1) Infection potential (2) vector potential and (3) transmission potential. [See this *Bulletin* 1942 v 39 616 and 1943 v 40 695] The details of experimentation should be consulted. After finding that a flea species was capable of transmission the procedure was to feed the laboratory reared flea infected from an animal with a known bacteraemia, daily on single white mice as long as the flea lived. An example will make the mode of calculating efficiency clear. If 100 fleas of the same species are given an opportunity to become infected and 80 of them acquire the infection, the *infection potential* would be 0.80. If of the 80 infected fleas 40 became infective the *vector potential* would be 0.50. If the 40 infective fleas transmit the infection 80 times the *transmission potential* would be 2. The product of these potentials—0.80 0.50 and 2 represents the vector efficiency of the species tested. Four species of fleas were tested individually and gave the following vector efficiencies *Ctenocephalides felis* 0.1; *Hoplopsyllus anomalus* 0 *Xenopsylla cheopis* 0.43 and *Diamanus [Ceratomyx] montanus* 0.84.

RUMREICH A. S & WYNN R. S. A Study of the Rodent-Ectoparasite Population of Jacksonville, Fla. *Pub Health Rep* Wash. 1945 Aug 3 v 60 No 31 885-905 2 figs [40 refs.]

SAVINO E. Aplicación al hombre de la vacuna antipestosa cepa E. V de Girard. [Living Plague Vaccine for Man.] *Bol Sanitario*. Buenos Aires. 1943 Apr.-June v 7 Nos. 4 5 & 6, 103-11

It is evident that the use in vaccination of living non-virulent, but immunizing plague strains is making headway. The strain employed in the province of Córdoba, Argentina, was the E.V strain of GIRARD. Thirty persons were vaccinated and careful notes made of reaction with the following conclusion. None of the persons suffered any grave disability, all were able to continue at their daily work in spite of some pain, a little rise of temperature and local reaction. With the subsidence of this reaction there remained a small subcutaneous nodule. The author approves of the vaccine on the ground of its efficacy, experimentally in the guinea pig and of some years application in man. It should find a use especially in those districts where climatic conditions are favourable to development of plague outbreaks. *W F Harvey*

BACILLARY DYSENTERY

LAWRENCE E. A. & BENNETT R. E. A Study of Diarrhoea occurring at Army Air Force Headquarters, Calcutta, India. *J Amer Med Ass* 1945 Sept. 15 v 129 No. 3 194-6.

An American air base was situated on the Hooghly River in the midst of a densely populated (about 14 000 persons within half a square mile) collection of Indian villages where extremely insanitary conditions prevailed. The village streets and fields are littered with all kinds of debris. Decaying garbage, human and animal excreta and occasional foul-smelling carcasses of dogs and bullocks left lying for days at a time are the usual conditions found.

From January to June 1944 569 soldiers reported sick with diarrhoea and in July there were 205 cases the sudden increase being due to the onset of the rainy season and increase in fly-breeding. A careful study of 198 consecutive cases of diarrhoea was made from July 11th to August 2nd, they included 31 cases of amoebic dysentery, 66 of bacillary dysentery and 7 of both amoebic and bacillary dysentery. Fever was present in 16 of the amoebic dysentery cases and in 31 of the bacillary dysentery cases, hence it has little diagnostic value. Tenesmus was present in 5 of the amoebic dysentery cases and in 19 of the cases of bacillary dysentery. *Shigella* organisms were isolated from 25 of the 66 cases of bacillary dysentery, no *Shiga* type was isolated.

Control measures included spraying of fly breeding places with DDT or pyrethrum, fly-trapping and screening of buildings and the resulting fly control was dramatic and gratifying. Indians working in and near mess halls were given a daily dose of carbarsone grain $\frac{1}{4}$ for 10 days, and repeated stool examinations were made on food-handlers. From August 2nd to 23rd there were 21 cases of bacillary and 11 of amoebic dysentery, a slight decrease only though there was a greater decrease in the total number of diarrhoea cases. American soldiers were also a reservoir of infection and, as many lived at the hotels for various periods, control could not be very complete.

The chief conclusions are that careful diagnosis is necessary so that thorough treatment may be given, and that sanitary discipline should be strictly maintained. *J F Corson*

BOSE A. N. & GHOSH, J. K. Sulphanilyl Benzamide in the Treatment of Bacillary Dysentery. *Indian Med Gaz.* 1945 June v 80 No. 6 293-4

Twenty-one cases of bacillary dysentery were treated with sulphanilyl benzamide. 16 were bacteriologically positive.

The total dose required was only 14 grammes (28 tablets) for complete cure except in two cases with Shiga infection which required a little longer treatment. Almost all the patients were fit to resume work within five days. Stool culture was done up to three months with negative results in all cases. No relapse was seen up to a period of six months observation. The drug is found to be non toxic.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

SOFIA F & CIARAVINO E. Inchiesta coprologica sui nativi dell Eritrea. [Faecal Examinations among Native Eritreans.] *Boll Soc Ital di Med e Igiene Trop* (Sez. Eritrea) 1944 v 4 Nos. 5-6 785-802. English summary (5 lines)

The authors have examined the faeces of 700 Eritreans in the Regina Elena Hospital Asmara. They discarded those with obvious intestinal disturbance in order to obtain a general idea of the degree of infestation among the people. They noted in each case the place of birth, changes of residence in recent years, occupation, and any history of earlier intestinal disturbance, but these points are not afterwards referred to in the record. The methods used were direct examination after a saline purgative and Willis's technique for helminthiasis and the Telemann enrichment method which gave much more satisfactory results.

The chief findings were: *E. histolytica* in 209 (29.8 per cent.), *E. coli* 187 (26.7), *Trichomonas* 46 (6.5), *Chilomastix* 27 (3.8), *Giardia intestinalis* 15 (2.1). The figures for *E. histolytica* are compared with a selection of those recorded from time to time in other parts of the world, notably United States 11.6 (Craig), Brazil 9.3 (Pestana), Alexandria 13.7 (Wenyon & O'Connor), India and Mesopotamia 19.9 (MacAdam), Dutch Indies 24.0 (Brug), Jamaica 14.7 (Scott), Shanghai 10 (Fischer), and Venezuela 30 (De Bellard).

Balantidium coli was found once only. Of helminthic infestations the commonest was *Trichuris trichiura* 207 (29.5 per cent.) and next in order *Ascaris lumbricoides* 134 (19.1), *Ancylostoma duodenale* 132 (18.8). *Necator americanus* has been recorded by others, but the authors did not meet with a single instance. *Taenia saginata* 58 (8.2), *Hymenolepis nana* 34 (4.8) and *Enterobius vermicularis* 24 (3.4). All these were diagnosed by finding the ova in the faeces. *Schistosoma mansoni* was found 6 times only (0.8 per cent.). Finally *Blastocystis* was seen in 21 (3 per cent.) H. Harold Scott

SHIH LU CHANG. Sedimentation in Water and the Specific Gravity of Cysts of *Entamoeba histolytica*. *Amer J Hyg* 1945 Mar v 41 No 2 156-63. 2 figs. [10 refs.]

In a specially designed chamber (2×1.5×0.5 cm.) the rate of sedimentation of cysts of *E. histolytica* suspended in distilled water was directly followed by observation through a horizontally placed microscope. Readings were made with a micrometer eye piece. The sedimentation chamber was immersed during the observation in a mineral oil bath of uniform temperature in a larger glass chamber. The general result showed that in a sedimentation tank 10 feet deep at a temperature of 25°C cysts 15 microns in diameter would take approximately four days to settle. If water is subject to disturbances by wind or convection currents the settling time would be longer. Calculations by Stokes's law based on the settling rates, gave a specific gravity for cysts of

1-060. It seems evident that storage of water must be long if it is desired to remove cysts of *E. histolytica* by sedimentation. The paper (illustrated by diagrams) describes in detail the technique employed. C M Weyon.

MARUASHVILI G M On certain Differential Diagnostic Characters of Amoebic and Bacillary Dysentery *Med Parasit & Parasitic Dis* Moscow 1944 v. 13 No. 6 57-62. [In Russian]

A description is given of supplementary methods for the differential diagnosis of amoebic and bacillary dysenteries. It was found that counts of neutrophile leucocytes with toxic granules in blood films proctoscopy and examination of the cell picture in the mucus, are of great help in cases when the usual methods of diagnosis fail. In bacillary dysentery the "toxic granules" are coarse, occurring in 53-88 per cent. of the neutrophils in acute cases dropping to 16-47 per cent. in convalescents. In amoebic dysentery the granules are fine and they are found in 11-35 per cent. of neutrophils subsequently falling to 8-18 per cent. Proctoscopic examination is regarded as a most important method for determining the form of dysentery according to the morphological changes undergone by the mucous membrane of the large intestine. While amoebic dysentery is characterized by numerous solitary circular ulcers with uneven margins and a coating of whitish-yellow mucus in bacillary dysentery the entire mucous membrane is involved. It is covered with layers of brownish mucus over large superficial ulcers which are circular or transverse. Further data are provided by examination of the mucus removed in the course of proctoscopy. This sometimes reveals the presence of amoebae microscopically or of dysentery bacilli in cultures even when these cannot be isolated from the stools. Finally much information can be obtained from the cell-picture of the mucus. In acute amoebic dysentery there are large numbers of neutrophils erythrocytes macrophages and epithelial cells but eosinophils are absent however in convalescent cases the last named elements increase progressively in numbers, while the other elements decrease. On the other hand in acute bacillary dysentery large numbers of pus cells erythrocytes and changed epithelial cells are present in addition to macrophages crystals of fatty acids and bacteria. In convalescent cases of this disease the number of red blood corpuscles and pus cells diminishes visibly while that of macrophages and epithelial cells increases, and solitary eosinophils begin to appear. C A Horne.

CROPPER, C. F. J. Sigmoidoscopy in Amoebic Dysentery *Lancet*. 1945 Oct. 13 460-62.

The author who writes from India, points out that the disturbingly high incidence of chronic bowel disorders in those who have served in the East demands high competence in the handling of the dysenteries. He urges a more accurate study of the bowel lesions of amoebiasis.

Sigmoidoscopic examination is desirable for the diagnosis of chronic bowel disorders in patients who give a history of residence in an endemic area of amoebiasis in spite of the fact that the procedure has its limitations, and gives a negative result when there is active amoebic infection higher up.

It is not necessary in fresh, acute cases, in which diagnosis can usually be made by stool examination, but in other cases it may give much help. The symptoms of amoebiasis are so protean, that it is a precaution in—(1) Sprue (2) any case in which pulmonary amoebiasis is suggested (3) refractory enteritis and headache (4) hepatomegaly and unexplained loss of weight. It should never be overlooked.

The ideal room for sigmoidoscopy should be situated at one end of the dysentery ward. If the examination is timed for 9.30 a.m. the following enemas should be given—7.30 a.m. half strength soap enema 8 a.m. 2½ per cent sodium bicarbonate enema. This procedure gives a very clean surface. No sedation is needed. The patient should be in the genupectoral or left lateral position and while the tube is being passed up the bowel attention should be concentrated on manipulation the detailed examination being carried out during the process of withdrawal of the sigmoidoscope. For identification of the lesions a lens giving a magnification of 4-5 diameters is essential.

The classical amoebic ulcers vary in size shape and distribution from small areas 1/3 inch in diameter to almost total ulceration of several inches of bowel. The unit of ulceration is the classical flat shallow depression with undermined, congested edges and of irregular diamond shape. There is a yellow purulent membrane with bright blood oozing scantily from its cracks and edges. There is no correlation between the duration of infection and the severity of the symptoms on the one hand, and the extent of ulceration on the other. These ulcers respond readily to emetine.

Yellow-headed ulcers are those in which bright shining homogeneous sloughs are present they may be widely scattered and may be separated by mucous membrane of normal appearance.

Pin-point craters are the commonest lesions found and may remain after the healing of the classical ulcers. The area in which they most usually occur is from 3 to 7 inches from the anus. They are seen as small dots surrounded by heaped edges their average diameter is 1-2 mm. The valves are often affected, and the whole visible bowel may be peppered with them giving the appearance of an aerial photograph of bomb craters on an airfield. These craters are not described in most standard works on amoebiasis but though definite evidence that they are amoebic in origin is difficult to obtain the author considers that they may justifiably be taken to indicate active amoebic infection. They are very refractory to treatment but may gradually disappear losing the central depression and resembling flat topped cutaneous warts. For demonstration of these craters it is essential so to manipulate the sigmoidoscope that the mucosa is illuminated obliquely. [Pin-point ulcers occur also in rectal schistosomiasis see this *Bulletin* 1945 v 42 47]

Pigskin appearance is a term applied to minute scattered pits, resembling pin-pricks on the surface of Plasticine the pits are very persistent but may disappear. There can be little doubt of their amoebic origin.

P Manson-Bahr

SILVERMAN D N & LESLIE A Intractable Amoebic Colitis, with special reference to the Ulcero-necrotic Form. *J Amer Med Ass* 1945 Sept 15 v 129 No 3 187-90 3 figs.

The term ulcero-necrotic has excellent descriptive qualities but should be reserved for the type of case of which three are presented in this paper.

In the first two *E histolytica* trophozoites were demonstrated in all layers of the colon from mucosa to serosa. In the third there was demonstrable extension to the submucosa. An unusual feature was the involvement of the entire colon in the ulcero-necrotic process which in the past has seldom been observed in America.

The first two were complicated by secondary infections with dysentery organisms Flexner in one and Duval (Sonne) in the other. It is possible, though not necessarily probable that this combination of pathological processes results in the diffuse ulcerating and necrotizing process which in one

case caused a major slough of the transverse colon and in the other a large mucosal slough of the recto-sigmoid.

Though the third case did not present the striking features of the other two the fact that the entire colonic mucosa was destroyed by the ulcerative process warrants its inclusion in the series. All these cases were fatal, and details of autopsy findings are given.

Case 1 ran a sudden and acute course of less than three weeks duration. The patient was febrile and severely ill. Six days after admission he passed a large tissue slough by rectum. The diagnosis was rupture of the ascending colon complete sloughing of the wall of the transverse colon intense ulceration of the whole colon suggestive of bacillary dysentery acute inflammatory hepatitis general peritonitis acute toxic splenitis and nephritis.

Case 2 had febrile diarrhoea with generalized abdominal pain for a year with exacerbation of one week.

The distal foot of the ileum showed occasional shallow ulceration. The wall of the colon was decidedly thickened, and except for an occasional patch of red oedematous mucosa, had been completely undermined by acute and long-standing chronic cellulitis.

Case 3 a man of 68 was undergoing radiotherapy treatment for carcinoma of the bladder. He had in addition a febrile bloody diarrhoea of two months duration.

The colon was adherent to the surrounding structures there were many areas of necrosis, but no area of complete perforation. The mucosa was destroyed by ulceration which involved the entire bowel, including the caecum and rectum. Many amoebae were seen in microscopic sections in the necrotic zones.

An increase in incidence of this type of case in the United States may be foreseen as a result of the local dissemination of amoebiasis, and the importation of virulent strains of amoebae from the oriental and tropical theatres of war
P. Manson-Bahr

DE SILVA, S. "Significant Observations on Amoebic Hepatitis"—a Clinical Review of 200 Patients. *J Ceylon Branch Brit Med. Ass.* 1945 Apr., v 41 No 1 21-6 3 charts.

In the General Hospital, Colombo the number of cases of amoebic hepatitis liver abscess which averaged 88 in 1929 had swollen to 1,279 in 1944 the manifestations assumed so many different forms that they have afforded a rich field for investigation. In almost all cases the therapeutic test response to emetine injections supported the clinical diagnosis. In a series of 200 cases pathological confirmation was obtained in 60 and X-ray confirmation in 45.

About 70 per cent. were admitted with pain over the right lower chest this, together with sudden onset, high fever scanty crepitations and occasional pleuritic rub suggested pneumonia, and recourse was had to sulphapyridine therapy without success but directly emetine injections were substituted symptoms subsided. Previous and recent alcohol consumption is considered important. 178 patients confessed to excessive amounts over a period of 5-20 years, and it is suggested that alcohol may precipitate acute hepatitis in hitherto symptomless carriers. In 25 per cent. there was a history of vague abdominal pain, causing rigidity or guarding of the right rectus muscle and the amoebic splash in the right iliac fossa. Occasionally symptoms suggested an acute abdomen with appendicular colic—one with an anterior liver abscess simulated perforated gastric ulcer. A palpable epigastric tumour became apparent in 38.

In 68 the hepatic abscess was aspirated through the intercostal spaces but in 12 further operative interference became necessary in three a blood stained pleural effusion at first suggested carcinoma. Previous dysentery was recorded in 52 during a period of 3-5 years and the impression was obtained that a recent relapse determined the onset of hepatitis. In 12 the symptoms at first suggested haemorrhoids.

The pain of hepatic amoebiasis is dull especially noticeable on deep inspiration or on coughing causing the patient to incline to the left side. It is localized to the right lower intercostal spaces over the area occupied by the liver. Pain referred to the right shoulder or neck in 44 constituted a prominent symptom. Hepatitis pain is never referred to the lower abdomen as may happen in basal pneumonia or pleurisy. It is intensified at night aggravated by alcohol by deep breathing and increased by percussion.

The increasing numbers of hepatitis cases are attributed to incomplete treatment of amoebic dysentery.

P Manson-Bahr

SPADARO O. *Lepatite amebica (studio clinico)* [Clinical Study of Amoebic Hepatitis.] *Boll. Soc. Ital. di Med. e Igiene Trop.* (Sez. Entrea) 1944
v. 4 Nos. 5-6 825-47 5 figs [105 refs.] English summary (8 lines)

The author's statements are based on 50 patients treated in the Regina Elena Hospital Asmara during the 5 years 1939-44. Forty were Europeans and 10 were Eritreans. Each year an average of 216 cases of intestinal amoebiasis has been found by microscopic examination and this is below the real amount of infection for statistics show that 29.8 per cent. of presumably healthy subjects yield positive findings of *E. histolytica* in their faeces [see SOFIA and CIARAVINO above]. In this connexion it is worth noting that of the 50 referred to in the present paper only 24 had given any history of an earlier enterocolitis and 21 were passing amoebae in their stools. Nine of the series, who had actual liver abscess and entamoebae in the stools, declared that they had never suffered from diarrhoeal attacks of any note and 16 patients (12 of them Europeans) had never had any intestinal disturbance of any importance although the entamoeba was present in their stools.

Nine of the 50 died they had for long had enlarged livers. In 48 the abscess was in the right lobe. Early symptoms were debility dyspepsia and enlargement of the liver with fever. Anorexia nausea and vomiting were often but by no means always present the same applies to shivering attacks and sweating. Subicterus was present in 10 true jaundice in three only. Pain may be very acute and limited to the lower border of the liver in others it may be more intense in the 9th and 10th intercostal spaces in the axillary line. Right-sided basal pleurisy was not infrequent. Leucocytosis was not very marked up to 16 000 per cmm. in colliquative hepatitis. Radiology is of great help in diagnosis a marked feature being immobility or restriction of movement of the diaphragm on the affected side with enlargement of the liver. The chief complications are secondary infection spread of the abscess and opening into the lung. Prognosis depends much on whether the abscess is single or multiple. OCHSNER's figures are quoted of 100 per cent fatality in multiple cases and 10.5 per cent in unilocular abscess. Another important point in prognosis is the treatment adopted. In the old days of ipecacuanha the fatality rate was about 12 per cent after emetine came into common use it was from 2.6 to nil. DOMINICI in Italy had a rate of 0.8 per cent. among 114 cases [one death presumably]. Other figures quoted are 38 cases with medical treatment and hepatocentesis 5.26 per cent 38 with surgical and medical treatment combined 28.42 per cent. 17 with surgical treatment alone 29.92 per cent.

The author's patients have been treated with emetine 90 cgm. in all three injections are given daily each of 3 cgm. after 45 cgm. have been given (5 days) an interval of 10 days is allowed to elapse during which stovarsol or yatren is given. In the colliquative forms the emetine treatment is combined with evacuation of the abscess cavity and washing out with a solution of emetine. Good results have followed collapse therapy of the abscess cavity by means of Potain's aspirator. Cures have been attained in 20 days in this way but emetine treatment has been maintained by a course every three months for about a year. Details of six cases are given in an appendix.

H. Harold Scott.

PICARD H. & BENSIMON T. Skin Amoebiasis. *Acta Med Orientalia (Palestine & Near East Med J)* 1945 Aug v 4 No 8 282-4

Amoebiasis of the skin is easily diagnosed if suspected but is often unrecognized. It is almost certainly fatal if specific treatment is not given but treatment with emetine is effective.

It is probably not extremely rare as 74 proved and 28 suspected cases were reported in 1940. In the present paper the authors record 7 cases in 5 of which [4 according to the text] *E. histolytica* was found. The areas of skin affected were at the incision for operation for liver abscess (1) at the incision for appendicectomy (2) and the perianal skin (1).

The authors think that a debilitated state of health increased virulence of the amoebae and perhaps the presence of other infections may be contributory causes.

Treatment is by emetine injections in very rare cases where this may fail, wide excision of the area may be required.

"In a case of amoebic pericarditis subsequent to extension of an amoebic abscess of the liver the clinical impression was that of tuberculous pericarditis and the diagnosis was established only at autopsy."

EDINGTON A. D. A Simple and Practical Method of treating Amoebiasis. *South African Med J* 1945 Aug 25 v 19 No. 16 294

The treatment recommended in this paper is presumably intended for cases of chronic amoebiasis of the intestine as it does not prevent the patient from doing his daily work. Emetine bismuth iodide is given in 3-grain doses on an empty stomach early in the morning accompanied by a drink of half a tumbler full of ice-cold water. The patient at once lies on his right side and remains so for an hour. This dose is given daily for 10 days. The course is followed by a carba[r]zone treatment of 20 tablets which are taken twice a day [0.25 gm. *bis die* for 10 days?] and if the patient finds HCl does not induce dyspepsia or heartburn he takes 5-15 drops in a large drink of water after each meal.

The author treated 107 patients suffering from amoebiasis and most of them were able to enjoy their breakfast during the course. A few vomited once or twice and in some the drug caused mild diarrhoea, but all completed the course. At the end of treatment only two patients showed a few cysts and only one had any toxic effects—mild sciatic pains in the legs. No relapses have occurred in the cases followed up.

The gastric juice was examined in 67 cases of amoebiasis the great majority of these patients had hypochlorhydria and several had achlorhydria while only two had ' a very slight degree of hyperchlorhydria. J F Corson

PESSÔA S B & AMARAL, D F Ação da emetina sobre a *Entamoeba histolytica* em cultura como teste do seu valor amebicida. [Action of Emetine on *Entamoeba histolytica* in Culture as Test of its Amoebicidal Value] *Brasil Medico* 1945 July 7 & 14 v 59 Nos 27 & 28 241-4 English summary

The authors have found that *E. histolytica* will grow well in a medium consisting of a solid base of coagulated ox serum covered with Locke's solution to which a quantity of defibrinated ox blood has been added. The amoebicidal action of emetine and cephalin were tested by adding solutions of various strengths to cultures maintained at a pH of 7.4 to 7.6 and at a temperature of 37.5°C. It was found that emetine was amoebicidal and hindered growth when the concentration in the medium was 1 in 20 000 while cephalin ceased to be amoebicidal at a dilution of one in 10 000. The action of cephalin was not altered by boiling or autoclaving the solution before testing it.

AMIN N MAHFOUZ M & SHERIF M A F The Pharmacological Action of Quassin as compared with Emetine *Quart J Pharm & Pharmacol* 1945 Apr-June v 18 No 2 116-21 4 figs.

The author has made a pharmacological study of quassin and compared it with emetine hydrochloride with special regard to its action in causing depression of the heart and a lowering of the blood pressure. He has also studied the action on cilia of the toad's buccal membrane trichomonas from the caecum of guinea-pigs and *Entamoeba histolytica* from cases of amoebic dysentery. In all these tests quassin was superior to emetine. It proved to be non-toxic to animals in large doses and only depressed the heart and lowered the blood pressure in high concentrations. It was also more effective than emetine in its action on the cilia and the protozoa. Quassin was accordingly tried by intramuscular injection in certain cases of acute amoebic dysentery and the results are said to have been encouraging. [It seems exceedingly doubtful if *in vitro* observations on amoebae and trichomonas while in faeces justify conclusions as to the relative activity of the substances tested.]

LÄNG S Ueber die intravenöse Urotropinbehandlung der Lamblija-Cholecystitis. [Treatment of Giardiasis Infection by Intravenous Injections of Urotropin.] *Schweiz med Woch* 1945 Aug 4 v 75 No 31 679-80

The author discusses the various views that have been held regarding the pathogenicity of *Giardia* particularly from the point of view of cholecystitis. He notes that some observers consider the main habitat of the flagellate to be the duodenum while others hold that the gall bladder is the main seat of infection. Observers are fairly well agreed that when samples of bile are withdrawn by duodenal tubage it is in the B fraction that the greatest number of *Giardia* are found while it has been claimed that in three cases in which the gall bladder had been removed for cholecystitis the flagellates had been found in the bile inside this organ. Furthermore it has been observed that treatment with bismuth or stovarsol will cause the *Giardia* to disappear from the duodenum for some days but they reappear presumably because these drugs have no action on the contents of the gall bladder. The author admits however that other observer

have failed entirely to find the flagellates in gall bladders removed for so-called *Giardia* cholecystitis. He favours the view that symptoms of cholecystitis are due to invasion of the gall bladder and he is supported in this conclusion by his observation that in a number of cases intravenous injections of urotropine which is known to be excreted in the bile have brought about not only an eradication of the infection but complete relief from all symptoms. The treatment has consisted in the daily intravenous injection of 10 cc. of a 40 per cent. solution of the drug for four to six days. The action of the drug was controlled by duodenal tubage.

RELAPSING FEVER AND OTHER SPIROCHAETOSIS

STUART G. Relapsing Fever in North Africa and Europe, 1943-1945. *Epidemiological Information Bull* (UNRRA Health Division) Washington D.C. 1945 July 15 v 1 No. 11 453-64

The author refers to the epidemic of louse-borne relapsing fever recently present in Tunisia, Algeria and Morocco and gives a historical survey of outbreaks in that area and in other French African possessions since 1919. The present epidemic probably originated in Fezzan and began in Tunisia in September 1943. In 18 months there were 30 744 cases in Tunisia alone, and during the latter part of 1944 and the early part of 1945 there were 5 062 cases in Algeria and 667 in Morocco. The epidemic was still raging according to the last available returns, in February-March 1945.

In Tunisia the disease was at first mild, but as the epidemic extended, severity increased and the case mortality rate reached 10-12 per cent.

In Europe 578 cases of tick-borne relapsing fever were reported in 1943-44 from Spain and the louse-borne form has recently been recorded from Turkey, Rumania, N. Ireland and England. In Greece and France there have also been cases, the latter in maritime areas having connections with N. Africa. The tick-borne form is not uncommon in Tunisia where *Ornithodoros erraticus* is widely distributed and where *O. savignyi* (a potential vector) is found towards the south. *Rhipicephalus sanguineus* also a potential vector is found in Algeria.

Three recognized carriers of the disease have been recorded from Libya, viz. *O. moubata*, *O. savignyi* and *O. laborensis* [presumably *O. laborensis*]; it is said that tick-borne relapsing fever occurs there.

In the French experience of louse-borne relapsing fever stavarsol was ineffective but with novarsenobenzol or mapharsen the results were very good. The optimum doses for an adult weighting 60-85 kgm. were —

Novarsenobenzol — 0.6 gm. the first day 0.75 gm. the following day and one stimulating dose a week later.

Mapharsen — 0.06 gm. the first day and the same the following day.

Charles Wilcocks.

WOOD R. C. & DRYAN K. C. Tick-borne Relapsing Fever in Cyprus. *Brit. Med. J.* 1945 Oct 20 526-8 1 fig

The authors noticed that cases of relapsing fever were occurring in Cyprus among soldiers who had passed the night in caves or dungeons. A careful search of caves where infection had occurred revealed the presence of *Ornithodoros tholozani*, a known vector of relapsing fever which has not previously been recorded in Cyprus.

Twelve cases are described in detail. No lice were found on any of these patients, and in all cases there was either direct or indirect evidence of exposure

to the bites of ticks. The incubation period was usually 8 to 10 days. In two cases long periods of low continuous fever occurred as well as acute attacks of high pyrexia. Choroiditis was seen in one case and papillitis in four others. No other neurological complications were noted except changes in the cerebrospinal fluid. The urine was examined for urobilin in seven cases and marked urobilinuria found in six of them. All the cases were treated by intravenous arsenicals five relapsed but only two more than once.

In an appendix one of the authors K C D records that he had succeeded in infecting guinea-pigs by the inoculation of blood from another case of relapsing fever in Cyprus. This supports the view that the causative organism is *Spirochaeta hispanica* the tick borne strain of relapsing fever spirochaete which is found in other Mediterranean countries.

E Hundle

MARUASHVILI G M [On the Tick-borne Relapsing Fever] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 1 24-7 [In Russian]

This paper deals with the occurrence in the Caucasus of tick-borne relapsing fever which was first noted there in 1928 since when only a few cases have been recorded. The disease is caused by *Spirochaeta caucasica* and is transmitted by *Ornithodoros verrucosus* which is found exclusively in burrows and caves inhabited by wild rodents (*Pallasimus* [*Pallasomys*?] *erythroumus caucasica* [= *Mesonites erythroumus caucasica*?] *Apodemus sibiricus* and *Mus musculus*) representing the reservoir hosts of the infection. Man becomes infected only when coming into contact with these biotopes [habitats]. The author records his observations on seven patients who were admitted to an evacuation hospital with a mistaken diagnosis of malaria. The incubation period is 6-10 days the onset of the first paroxysm of fever is sudden and it lasts 2-4 days with a temperature up to 39-41°C. The subsequent paroxysms are usually of short duration lasting up to 10 hours and terminating abruptly with copious perspiration. These paroxysms may at first recur every other day or every third day resembling benign tertian and quartan malaria, but later the apyrexial intervals gradually increase in length sometimes lasting more than one month. The number of relapses may reach 12-15 the duration of the disease being up to 3 months. Among other symptoms the author notes a transient functional cardiovascular insufficiency nausea and even vomiting during the first paroxysms of fever. The reaction on the part of the spleen and liver is very slight and there are no characteristic changes in the blood picture.

In the early phases of the disease Caucasian tick relapsing fever can be confused with malaria. Its differential diagnosis is based on the finding of spirochaetes in the blood of the patient or in experimentally infected hamsters. The disease was treated successfully with osarsol in doses of 0.25 gm given three times a day during 3-5 weeks.

YAWS

TOMPSETT R. R. & KAUER G L. Penicillin Treatment of Early Yaws. *Amer J Trop Med* 1945 May v 25 No 3 275-6

Five cases of yaws in Melanesians of the New Guinea area were treated with penicillin. One patient was given 250 000 units in doses of 25 000 units intramuscularly every 4 hours while the other four each received 400 000 units in doses of 20 000 intramuscularly five times daily at intervals of 4 hours.

Spirochaetes could no longer be found 15 to 24 hours after the beginning of this treatment and the lesions healed within 3 weeks. The Kahn reaction remained positive during the few weeks of observation but could not be observed longer as the patients disappeared when the lesions were healed.

J. F. Corson

GUIMARÃES F. N. Penicilina e bouba (Framboesia, Pian Yaws) Dose curativa mínima. Redução do número de injeções diárias. Redução do tempo de tratamento pelo aumento das doses. (Nota prévia.) [Penicillin and Yaws.] *Brasil Medico* 1945 June 18 23 & 30 v 59 Nos. 24 25 & 26 221-4 6 figs. English summary

This is a short article published as a preliminary note but it considers several points of importance as shown in the subtitle the minimal curative dose, the results of using smaller doses or of using larger doses over a shorter period. Experimentally spirochaetes in animals had proved to be very susceptible to the action of penicillin so it was decided to test its action in human spirochaetoses.

First with doses of 150 or even 100 Oxford units intramuscularly administered every four hours clinical cure was obtained in 17 days the former with a total dosage of 15,300 units in a girl of 9 years the latter with 10,300 units in a girl of 10 years. Another child of 10 years was given 50 units every 4 hours over a period of 40 days (12,000 units in all) but without obtaining clinical cure.

Next tests were made to ascertain the results of reducing the number of daily injections. With doses of 400 units three times a day cure was obtained in 14-16 days i.e. with a total dosage of 16,800 and 19,200 units. With two injections daily each of 400 units clinical cure resulted in a child of 2 years after 16 days treatment and in one of 11 years after 23 days treatment. To two children a single daily dose was given one, a girl of 9 years received 3,200 units daily and was cured in 20 days. The other was the boy who had failed to respond to the 50 units every 4 hours after 40 days (see above) He was given a single dose of 1,600 units daily for 30 days (total 48,000 units) and was cured.

All the patients referred to above were children—the oldest was 11 years of age for adults the author states that these doses should be doubled.

Thirdly the trial of increasing the doses and reducing the period of administration was made. The dosage was graded according to the body weight. To a youth of 16 years weighing 42 kilos a dose of 46.7 units per kilo was given every 4 hours and cure was obtained in 15 days the same occurred in children of 4 to 12 years with doses of 33.3 units per kilo every 4 hours. It is to be noted that in none of these three were any spirochaetes seen in the lesions 72 hours after the treatment was started, but it was continued nevertheless for several days to consolidate the cure and to obtain reversal of the Wassermann reaction

LEPROSY

MARIANO J. Pênfigo bolho-esfolhativo e lepra. [Exfoliative Pemphigus and Leprosy.] *Rev. Brasileira Leprologia* S. Paulo. 1945 June v 13 No 2, 103-6 2 figs.

A leper woman of 42 years clinical type N1 developed a bullous rash on the thorax which was at one time thought to be pemphigus foliaceus but the

bullae were associated with ulcerating and scabbing areas 'The type and localization of the lesions by themselves rule out the possibility of Dühring's disease says the author [but dermatitis herpetiformis commonly occurs on the trunk] *H Harold Scott*

CAMPOS N S & SOUZA P R. *Lepra e sífilis Leprides sífilóides o sífilides lepróides. [Leprosy and Syphilis.] Rev Brasileira Leprologia S Paulo 1945 June v 13 No 2 77-94 17 figs.*

This paper deals with an important and puzzling question—the resemblance between certain lesions in leprosy and those in syphilis. Lesions may bear so strong a resemblance to each other—syphilis-like leprides and lepra like syphilides—that a wrong diagnosis is likely to occur and valuable time be lost before the appropriate treatment is undertaken.

The similarities are duly shown by the authors, notably the roseolar exanthem of leprosy to that of syphilitic roseola tuberculoid leprosy to certain late secondaries in syphilis. Distinctions on paper at least are not easily recognized, being matters of degree rather than of kind. Thus in roseolar exanthemata of leprosy the patches are larger than in syphilis and in the latter they are more homogeneous and equal in size and evolve more rapidly. As for the tuberculoid lesions they are less polymorphic in leprosy than in syphilis and their development is slower taking 6 to 12 months. The Wassermann reaction may help especially if negative but it may be positive in some lepers the clinching diagnostic point is the finding of the organism by biopsy.

Excellent photographs illustrate the paper but it must be confessed (by the abstractor at least) that they afford less enlightenment than one hoped. They bear appropriate legends otherwise it would be difficult to distinguish for example Fig 1 a tuberculoid leprosy from Fig 13 a late secondary syphilide. Cases of papulo-tubercular syphilis simulate it will be seen to an extraordinary degree instances of severe facial lepromata. To one photograph depicting the histological changes in a syphilitic is the legend granulation of tuberculoid structure indistinguishable histologically from that met with in tuberculoid leprosy *H Harold Scott*

LIMA L de S & CERQUEIRA, G de C. *Terapêutica experimental da lepra pela solutiazamida. [Treatment of Leprosy with "Solutiazamido" Rev Brasileira Leprologia S Paulo 1945 June v 13 No 2 97-100*

Solutiazamide is stated to be p (γ phenyl propyl amino) phenyl sulphamidothiazole x γ-disulphonate of sodium and prepared directly from sulphathiazole and is very readily soluble in water. A solution of 45.3 per cent. corresponds to a 20 per cent. sulphathiazole base. It was administered daily (except Sundays) intravenously in doses starting with 1 cc. and increasing up to 5 cc. or for adults 10 cc. After three weeks an interval of one week is allowed to elapse before the treatment is continued. The treatment is controlled by a blood count and haemoglobin estimation every 10 days examination of the urine and any deposit, and an estimation of the drug in the blood. If the red cells fall below 3½ million per cmm. the dose of the drug is reduced and liver preparations are given the urine is examined for blood and albumin or any indication of nephrosis and if it appears treatment is suspended.

The new drug was tried in 50 cases of moderately developed lepromatous forms and others more advanced. 50 cases of lepromata with skin involvement and lesions of eyes and nose and some in whom chaulmoogra had been tried ineffectually. The authors publish their results in order that others may be led to make trial of the drug. So far reported these results sound almost too

good to be true. The authors report rapid cicatrization of leprosy ulcers, cicatrization of fusing lepromata, disappearance of lepromatous infiltrations to the level of the skin, softening and disappearance of cutaneous nodules perforating ulcers are sometimes benefited the ocular lesions improve and do not relapse, nasal crusts disappear obstruction is relieved and dyspnoea subsides.

HELMINTHIASIS.

SHUMKIKO, A. I. On the Degree of Infestation of Vegetables and Fruit with the Eggs of Helminths in Samarkand. *Med. Parazit. & Parazit. Dis. Moscow* 1944 v 13 No 6 77-8. [In Russian.]

The author describes the results of examination of vegetables and fruit from the bazaars of Samarkand for the presence of eggs of helminths. Investigations were made at different periods in 1937/8 and 1942/3 using the following method. Each portion to be examined was carefully washed twice by hand in 500 cc. of tap-water (total volume of water=1 litre). The water was then passed through a metal sieve (diameter 2 mm) into a vessel in which the height of the water varied from 6 to 15 cm. The washings were allowed to settle for 2-3 days or longer after which the water was siphoned off and the deposit poured out into centrifuge tubes (1-2 cm per tube). After centrifugation for 3 minutes the supernatant water was decanted, Darling's reagent was added to the tube the contents were carefully mixed with a glass rod, and centrifuged again for 3 minutes. The surface film was then removed with a metal loop and examined under the microscope. The total number of samples of vegetables thus examined was 210 in which were found 44 oncospheres of tapeworms and four threadworm eggs.

A summary of recent work

BLACK, K. O. Cutaneous Schistosomiasis Involving *S. haematobium* Eggs. *Brit. Med. J.* 1945 Oct 6 453-6 3 figs.

This interesting paper records the occurrence of bilharzial skin lesions on the trunk of certainly two and probably four of 130 male Europeans harbouring *S. haematobium*. All four cases were presumably heavily infected with the parasites as they had been repeatedly exposed to cercarial attack over a period of a month or more in West Africa. Each experienced skin sensations and developed skin lesions at the time of infection and each went through the classical febrile reactive stage of bilharziasis before ova appeared in the stools some three months after the initial infection. In only three of the four cases did ova subsequently also appear in the urine.

Case I—On being specifically diagnosed was promptly treated with 40 cc. of stilbophen intramuscularly over a period of 15 days. On the seventh day of treatment he drew attention to some herpetiform lesions in the skin below the right nipple. Shotty papular lesions then developed on the lower chest upper abdomen, lower back upper buttock, scrotum and perineum. Repeated aspirations of the lesions yielded *S. haematobium* eggs on many occasions.

Case II—On diagnosis by stool examination was also immediately treated with stilbophen. Again, one week after starting treatment, papular lesions were

noticed in this case in the left lumbar region. Similar lesions appeared on the lower left chest and these on aspiration yielded *S. haematobium* ova. Four further clusters of lesions and some scattered isolated papules developed in the left lumbar, the sacral and gluteal regions in this case.

Case III was a mixed *S. mansoni* and *S. haematobium* infection with two similar clusters of papules in the lumbar region but ova were not recovered from these.

Case IV was also a *S. haematobium* infection, with a group of spots to the right of the umbilicus but here again ova were not recovered from the lesions.

Owing to the similarity of the skin manifestations in all four cases it is reasonable to assume that all were of similar origin.

The author in discussing the matter points out the similarity at some stages of the skin lesions he describes to those seen in the bladder or the bowel on endoscopy and he believes they resemble the cutaneous manifestations described by MADDEN [this *Bulletin* 1919 v 14 339] and by GIBGES [*ibid* 1934 v 31 907]. In his own cases however the lesions did not go on to the ulceration and sinus formation described by these authors. He speculates on the route by which the worms depositing the causative ova reached the site of their recovery in the skin and suggests that they may have ascended the scrotal, gluteal and lumbar veins from the iliac veins and vena cava, or travelled by the venous communications between the lumbar and epigastric veins or by the inferior epigastric from the external iliac veins. Some of the recovered eggs were dead and degenerate others were healthy and viable.

MILLER, S. E. *Schistosoma Hematobium* Infection. *J Amer Med Ass* 1945 Sept. 29 v 129 No. 5 344-7 5 figs.

Report of a case

MARIANI TOSATTI G. Bilharziosi intestinale da Sch. Mansoni in Eritrea. Descrizione clinico-anatomo istologica. [*Schistosomiasis mansoni* in Eritrea.] *Boll Soc Ital di Med e Igiene Trop* (Sez. Eritrea) 1944 v 4 Nos. 5/6 803-13

In 1936 Dr SATTA noted and recorded the presence of *Schistosoma mansoni* in the higher levels of Eritrea [this *Bulletin* 1936 v 33 553 953]. The author remarks that Clayton LANE maintained that this schistosomiasis was absent from Eritrea. [This is a mistake which the present author should not have made. Lane had stated (*ibid* p 11) as regards Eritrea, 'no accounts have come to light' and this as Lane maintained (p 953) is very different from affirming that the infestation is non-existent.] Three new cases are here recorded, two from the neighbourhood of the original focus in the Marazzani Concession, the third from near the village of Toselli 4 kilometres from Decameré. All three were in children 10 years old. The first two had bathed in the same stream, had felt intense itching of the legs and later suffered from fever, urticaria, and muco-sanguineous diarrhoea with abdominal pains. The symptoms persisted for some months but after coming to hospital, the patients were treated with Fouadin and made good recoveries. The third child bathed in a brook near his home. He felt severe itching especially on the legs and 10 days later had a very irritating diffuse red rash and, a few days after diarrhoea with four to six motions daily containing mucus and blood. He had previously suffered from taeniasis and he passed some proglottides. He was now treated for this last with satisfactory result. He seemed better for 3 weeks or so but then became rapidly worse with malaise, shivering, intermittent fever and muco-sanguineous diarrhoea within the next fortnight he

became pale, lost weight and suffered from an irritating cough and shortness of breath, was admitted to hospital (three months after the incriminated bathing) and he died a fortnight later. At autopsy the lungs showed nodular infiltrations containing ova of the schistosome, as did also the peritoneum. The general structure of the liver was retained but the central parts of the lobules showed intercellular oedema, the Kupffer cells were increased in number and were stuffed with black granules. In the sinusoids were small-cell infiltrations and there was general biliary cirrhosis. The spleen showed marked increase in the reticular tissue and some increase in the trabecular connective tissue. The organ was enlarged and weighed 300 gm. The intestine had a much thickened mucosa, stuffed with ova "about 60 per field" & few were present also in the muscular layers. The kidneys revealed nothing particular to note.

KHALIL BEY M. HALAWANI, A. & GAMAL NOR EL DEEN. The Problem of Post-Antimony Jaundice in Egypt. *J Roy Egyptian Med Ass.* 1945. *xxv* v 28, No. 5 192-208. [13 refs.]

Following the mass treatment of the population in one district in Egypt for bilharziasis with two trivalent antimony compounds, jaundice occurred in a number of patients. About 3 per cent. were affected in 8,000 cases treated with tartar emetic given intravenously while there was only one case of jaundice among 2,000 cases treated intramuscularly with stibophen. The jaundice occurred 1-3 months after treatment the greatest incidence being at the end of the longer period. The condition was accompanied by slight fever and certain constitutional disturbances among which gastro-intestinal symptoms were marked, and the period of upset lasted several weeks. Clinically the cases resembled those due to infective hepatitis but the incubation period was longer. It was later found that jaundice has occurred in some communities in the absence of antimony treatment. The presence of infective material in imperfectly sterilized syringes was therefore suspected, and this view appeared to be confirmed when adequate measures for their sterilization were introduced.

LAPTEV, A. A. [Strongyloidiasis of the Lungs.] *Klinicheskaja Meditsina* Moscow. 1945 v 23 No 3 75-6. [In Russian.]

The author describes a subject infested with *Strongyloides* [the species is not stated] in whom the symptoms were pulmonary. Intestinal symptoms being absent. Larvae of *Strongyloides* were found in the sputum only.

The subject was a Moscow carpenter aged 34 who had not left that city. At first he suffered from sharp attacks of dyspnoea with slight cough and expectoration of small quantities of odourless muco-purulent sputum which was free from blood. His temperature was 37.8 to 38.3°C. A slightly-itching urticaria appeared over the whole body followed by oedema of the face and lower extremities both these lasted only 24 hours. The next day the subject's condition was serious. In hospital a general examination revealed little except bubbly râles in the right scapular region and, by X-ray a diffuse, inconspicuous darkening of the whole right pulmonary field, especially in the region of the right scapula. Right-sided bronchopneumonia was diagnosed.

There was an eosinophilia of 22.5 per cent. Neither *Strongyloides* nor its eggs were found in the faeces but freely moving mature *Strongyloides* were found in the sputum. On the sixth day after admission to hospital 3-20 specimens per preparation were found but three days later there were only isolated specimens. Two days later still neither *Strongyloides* nor its larvae could be found in the sputum.

The bronchopneumonia was treated with 1.0 [presumably gm.] of sulphidine [sulphapyridine] four times daily but the subject's condition continued to be grave the high eosinophilia remained and some 50 cc. of sputum were voided in 24 hours. More careful examination of this sputum revealed mature *Strongyloides* in it. The subject was then given 20 cc. of 33 per cent alcohol intravenously and simultaneously 0.1 [presumably gm.] of methylene blue by the mouth in gelatine capsules. After three such doses of alcohol the dyspnoea decreased the sputum came away freely the cough improved and the temperature became normal. In the sputum only isolated *Strongyloides* were found and after eight doses of alcohol they completely disappeared. A total of 20 such doses of alcohol was given. The methylene blue was continued for 15 days. Eventually the X-ray picture of the lungs became normal. *Strongyloides* could not be found in the sputum and the subject was discharged in very good condition.

The author remarks that *in vitro* extract of male fern kills larvae of *Strongyloides* in 10 minutes. After mentioning various remedies for strongyloidiasis the author refers to Faust's opinion that gentian violet has a specific action on *Strongyloides* [cf. CRAIG and FAUST Clinical Parasitology 3rd edn. 1943 p. 253 London: Henry Kimpton] where intravenous administration of not more than 25 cc. of 0.5 per cent aqueous solution of gentian violet on alternate days for not longer than ten days is recommended for pulmonary infestation with *Strongyloides*.

HILMY I. S. The Effect of the Flooding Method of Sewage Disposal on the Viability of the Eggs of *Ascaris lumbricoides*. J. Roy. Egyptian Med. Ass. 1945 May v 28 No 6 207-14.

The health authorities at Cairo are concerned as to the possibility of disease being spread from the use of human excreta for fertilizing purposes. Biological treatment of sewage will destroy pathogenic organisms but the question of the survival of *Ascaris* ova is another matter since this ovum is one of the most resistant of all helminthic ova and the worms are very fertile. Before the

Flooding method of dealing with sewage was introduced these ova would survive without much difficulty. Now the following is the procedure. Liquid sludge and scum from sedimentation tanks are pumped on to drying beds each of an area of 49 sq. metres and spread as a thin layer and left to dry for 5 days in summer, 8 days in early spring and late autumn. Then another layer is applied and so on till as many as 20 layers may have been deposited. It is then covered with half an inch of sand and flooded with sedimented sewage and left for a fortnight then turned over and in 2-3 days (in summer) the whole is dry enough to distribute as manure. Thus about three months are needed for the whole process.

Examinations for viable ova of *Ascaris lumbricoides* were made after the four 3-monthly periods. Briefly stated, the results were that no viable eggs were found in samples from the beds prepared from March-June, June-September and September-December but they were present in those prepared in the remaining quarter December-March after 10 days storage. After 25 days storage by the ordinary piling method in this last period viable eggs were still

present but not after 30 days storage. The latter is therefore more economical for the December-March period and this is fortunately not the fly-breeding season the Flooding method is best for the rest of the year. It is not only a good method of sewage disposal but the fertilizer resulting therefrom is safe and free from viable eggs of *Ascaris*.

NEWTON W. L., WRIGHT W. H. & PRATT I. Experiments to determine Potential Mosquito Vectors of *Wuchereria bancrofti* in the Continental United States. *Amer J Trop Med* 1945 May v 25 No 3 253-61 [12 refs.]

As many American soldiers and sailors have returned to the United States suffering from filariasis the authors made experiments to see whether mosquitoes in the United States could transmit the infection the experiments were begun in Porto Rico with species of mosquitoes common to that island and to the United States and later were continued in Alabama.

Between July 1943 and October 1944 a total of 2,371 mosquitoes, comprising 16 species, fed on infected volunteers a short description of the feeding peculiarities of each species is given. After various intervals, beginning 9½ days after feeding, the mosquitoes were killed and dissected the wings and legs were removed and the mosquito was divided into abdomen thorax and head and these parts were tossed in normal saline under the dissecting microscope.

The development of the microfilariae corresponded with the textbook descriptions in most of the species in which full development took place it was complete within two weeks.

Altogether 1,801 dissections of 15 species and 49 of *Culex tarsalis* were made the former being shown in a table the latter being added in a postscript. The results indicated that *Culex quinquefasciatus* [*C fatigans*] *Culex tarsalis* *Psorophora confinnis* and *Anopheles albimanus* would be excellent vectors in favourable conditions. *Culex nigripes* *Aedes aegypti* and *Aedes triseriatus* could convey the infection, but their low infectivity rates in this experiment suggest that they could not be important vectors. *Aedes sollicitans* *Aedes taeniorhynchus* *Aedes texans* and *Anopheles punctipennis* could not apparently transmit the infection. The results with *Anopheles quadrimaculatus* *Culex erraticus* *Culex salinarius* *Psorophora ciliata* and *Psorophora discolor* were inconclusive.

The potential infectivity rate of *Psorophora confinnis* of the United States was 80 per cent. while in the apparently identical mosquito of Porto Rico it was only 12 per cent. 104 mosquitoes of each race having been dissected the two

of strains of this species were apparently physiologically different.

J. F. Corson.

NEWTON W. L. & PRATT I. Experiments to determine whether Infective Larvae of *Wuchereria bancrofti* can migrate from the Abdomen of the Mosquito Intermediate Host. *J Parasitology* 1945 Aug v 31 No. 4 268-8.

The mosquito's legs and wings were removed, then a longitudinal incision was made along the lateral abdominal wall and a drop of saline containing from 1 to 7 infective larvae of *Wuchereria bancrofti* was placed on the incision the larvae entered the abdomen and the incision became closed within a few minutes. After about an hour the mosquito was divided into abdomen, thorax, head and proboscis and these parts were examined for the presence of larvae.

Migration was found to have taken place in 22 of 27 mosquitoes of 68 active larvae recovered, 32 were in the thorax, 12 in the head or proboscis and 24 in the abdomen. The time of migration varied greatly in one case a larva had reached the proboscis within 5 minutes while in another case it took 105 minutes.

naval hospitals and convalescent centres. The Marine Barracks had hospital wards and laboratories and the staff included medical specialists laboratory research workers and technicians nurses and corporals.

In many cases, partly owing to their previous sedentary or convalescent life there was a good deal of hypochondriasis with psychosomatic reactions in the course of time however and when the incurable psychoneurotics were removed, the general mental attitude of the men improved greatly. Two groups were compared those with signs or a history of recent filariasis and those who had returned to America 6 to 12 months previously and had been in hospital the former returned to active duty more easily than the latter. Men who had recently been in battle and had the classic symptoms of war neurosis or combat fatigue paid less attention to their filarial symptoms than those who had been psychoneurotic before they became infected.

The following conclusions were reached the disease soon dies out after removal of the patient from the endemic area rehabilitation is best obtained by a combined programme of military vocational, educational and medical training and supervision no impairment of sexual function has resulted from filariasis and severe sequelae have occurred in only 0.2 per cent. of cases in another year or so there should be no filariasis problem in the U.S.A.

SAPHIR, W. Filariasis. Early Clinical Manifestations. An Analysis of Thirty-Five Cases. *J Amer Med Ass* 1945 Aug 18 v 128 No 16 1142-4

The author studied 35 patients whose history and symptoms suggested that they were suffering from filariasis although no microfilariae were found in the blood.

The commonest early symptom was a feeling of numbness or weakness in an arm or leg which was apt to fall asleep especially at night. Soon afterwards aching developed in one or more limbs, particularly after doing heavy work this usually began in the axilla or groin and led the patient to discover his large and tender lymph glands in those parts. Later still the patient experienced periodically recurring pain in the axilla, arm, groin, thigh or scrotum, sometimes accompanied by swelling. These attacks lasted for varying periods, from a few hours to some days and were followed by intervals of a few days or weeks with freedom from symptoms during the day though nocturnal pain, especially in the testicle was often present. Finally the lymphatic glands became continuously palpable, though the degree of enlargement varied. This was the usual history during a month or two before admission to hospital no history of any feeling of general illness was given.

The axillary inguinal and femoral lymphatic glands on both sides were enlarged and tender in all the patients and other lymphatic glands were also affected in some patients. Centrifugal lymphangitis was not seen. Left-sided funiculitis occurred in 21 cases and in six of these there was also left-sided varicocele right-sided funiculitis was present in five. Ten had varicocele.

Lymph glands were excised in four cases they showed hyperplasia but no filariae. Eosinophilia (5-10 per cent.) was present in nine patients and these had no intestinal worms.

The author thinks that the symptoms observed permitted a presumptive diagnosis of filariasis to be made.

CULBERTSON J T ROSE H M & OLIVER-GONZALEZ J. Chemotherapy of Human Filariasis by the Administration of Neostibosan. *Amer J Trop Med* 1945 May v 25 No. 3 271-4

Thirty patients were treated with neostibosan in Porto Rico. Five were adult males and twenty-five were girls between 8 and 17 years old. All had

microfilariae in the blood at night and all but one were free from clinical symptoms. The total dosage of neostibosan ranged from 4.6 to 10.5 gm given intravenously in doses of 50 to 300 mgm (on alternate days for three injections and then six times a week) spread over 33-48 days. This dosage was well tolerated. At the end of treatment only two patients (whose night blood initially contained 3 and 9 microfilariae respectively per 60 cmm. blood) were free from these parasites. During the next six months however the microfilarial count declined steadily in most of the patients. After six months seven patients had become negative eight others showed a decrease in the number of microfilariae by at least 80 per cent. and in only one patient did no decline occur. Fifteen untreated young males were observed as controls. During the six months only one of these showed a decrease in the microfilarial count. [Although these results are of great scientific promise they do not justify the treatment of filarial patients with neostibosan as a practical therapeutic measure at present.]

LAWTON A. H. BRADY F. J. NESS A. T. & HASKINS W. T. Tests of Mercury and Antimony Compounds in *Dirofilaria immitis* and *Latemosoides carinii* Infections. *Amer J Trop Med* 1945 May, 25 No 3 263-9 1 fig.

Tests were carried out on dogs infected with *D. immitis* and on cotton rats infected with *L. carinii*. Mercury cyanide and mercury oxycyanide had no apparent antifilarial action in dogs even when given in toxic doses. Antimony compounds of various types were given to dogs in various dose schedules. The one which was most satisfactory as regards therapeutic action and freedom from toxic effects was 0.8 mgm of antimony per kgm body weight given intravenously each day. Presumably a certain threshold level of antimony must be maintained in the blood to kill the microfilariae. Of the different antimony compounds tried sodium antimonyl 4-tertiary butyl catechol sodium antimonyl d-arabitol and p-phenetidine antimonyl tartrate were the most active the blood being freed from microfilariae after 4-5 injections. However live adult worms usually persisted for many weeks afterwards the females usually showed degenerative changes in the uteri. Altogether 29 dogs were used in these experiments and 28 were freed from microfilariae by means of antimony compounds.

A small number of cotton rats infected with *L. carinii* were treated by intramuscular or intraperitoneal injections of antimony compounds. Cotton rats tolerate larger doses than dogs. The response to treatment was less rapid or complete. In rats treated with five compounds the adult worms were killed, but 10 per cent. of the microfilariae persisted in the blood until the rats were killed two months later. Four other compounds, which had proved effective against *D. immitis* in dogs were ineffective against *L. carinii* in rats. The acute toxicity of the compounds was tested by intraperitoneal injection into mice. The compound which had the most favourable ratio between therapeutic activity and toxicity was sodium antimonyl 4-tertiary butyl catechol.

RIDLEY H. Ocular Onchocerciasis, including an Investigation in the Gold Coast. *Brit J Ophthalm (Monograph Suppl V)* 1945 58 pp 27 figs. & 4 pls (3 coloured) [156 refs.]

This monograph has been written by an ophthalmic surgeon who has recently served with the forces in West Africa. He there availed himself of an opportunity to investigate the eye lesions resultant on *Onchocerca volvulus* infestation of man in an area where these are known to occur. The author regards ocular

onchocerciasis as more terrible in its effects than the far more widespread trachoma. He deplors the lack of appreciation of its importance as a source of blindness throughout the major portion of the British Colonial Empire. It has been shown that filarial blinding is prevalent in certain limited areas of the Belgian Congo though the parasite is found extensively in this territory. In West Africa it is equally prevalent but, until very recently it has not been recognized to what extent blindness is here attributable to it. The tendency up to now has been to regard onchocercal blinding as an extreme rarity in West Africa, a view which Radley does not share.

After briefly outlining the historical aspect of onchocerciasis and delimiting its geographical distribution, the author gives an account of the morphology, life-cycle and mode of transmission of *O. volvulus*. He mentions the various anatomical sites in man from which the adults and the microfilarial forms have been recovered. The view is expressed that effective intermediate hosts other than *Simulium* spp. may exist (though no evidence is given for this belief) and the author is concerned about the possibility of extension of the range of the parasite beyond its present geographical confines as a result of troop movements into and out of the various endemic areas.

The clinical manifestations of the disease and its diagnosis are covered and the author goes with considerable detail into the eye changes he encountered in over 300 natives examined for onchocerciasis at Fumel in the Northern territory of the Gold Coast. Of these cases, 181 had onchocercal nodules and five others were found to be suffering from ocular onchocerciasis but had no discoverable nodules. Of these 186 cases of onchocerciasis among the 300 persons examined for the disease, 51 had ocular manifestations. Visual defect ranged from blindness or near-blindness in 22 persons through varying degrees of visual defect to good sight in 29 of the 51. The author points out that the proportion of eye defects in his series may be misleading as he saw possibly a selected portion of the population in view of the known aims of his visit.

The examinations were made under difficulties in the bush but a microscope and some ophthalmic equipment, including a slit lamp were available. To the author's regret he was not permitted, owing to native prejudice to excise a blinded eye for subsequent thorough pathological examination. His detailed account of the ocular pathology of onchocerciasis is therefore largely based on the literature. But, from this and from his own slit lamp observations he states that there is now no doubt that all onchocercal ocular lesions are caused by toxins released locally by dead microfilariae and that the living microfilariae set up no tissue reaction.

The author's observations on his 51 Fumel cases are recorded in tabular form, and fuller clinical and pathological details are given of the 22 cases with gross visual impairment. In addition to the cases at Fumel, the author found 16 African soldiers and four African civilians in Accra to be suffering from ocular onchocerciasis. Some of these men came from reputedly non-endemic areas. In describing the differential diagnosis of onchocerciasis the suggestion is made that the keratitis, uveitis and choroïdo-retinitis attributed to trypanosomiasis may in fact be due to a concurrent onchocerciasis and not to the trypanosomal infection. Radley states that personal examination revealed no ocular complications other than mild papilloedema in just over 100 cases of trypanosomiasis in the absence of an onchocercal infection.

The opinion is expressed that there is no effective treatment of onchocerciasis and that even removal of the nodules is of limited value as the individual microfilariae can survive for long periods (in one quoted case for at least 8 months) after excision of all known nodules. The author points out the difficulties in the prevention of the disease and concludes by reiterating

its gravity. There is a comprehensive bibliography appended and there are good microphotographs and photographs in the text. A. R. D. Adams

GETZ L. Massive Infection with *Trichuris trichiura* in Children. Report of Four Cases, with Autopsy. *Amer J Dis Children* 1945 July, v 70 No 1 19-24 1 fig [Refs. in footnotes]

Routine examination of stools reveals a high incidence of *Trichuris trichiura* in Panama [presumably in children especially]. Exact statistics are however not available. The author quotes the study of 160 cases of infection of children with multiple intestinal parasites by EINHORN MILLER and WHITTIER (this *Bulletin* 1945 v 42 911) and a clinical survey of trichuriasis in children to be published in the same journal by the same authors.

Getz analysed 1,307 autopsies which he did between 1924 and 1929. Among these subjects 374 (28.6 per cent.) harboured worms and among these 374 *Trichuris* occurred either alone or together with other intestinal parasites in 100 (7.6 per cent.). The maximum number of parasites found in any one subject was 400 and the heaviest infestations occurred in children. The author gives a valuable survey of the literature about trichuriasis and concludes that *Trichuris* may cause serious symptoms and physical signs, especially when infestations with it are massive as they may be in young children in Panama. The four subjects described in this paper support this view.

The first subject was a mestizo girl aged 13 years weighing only 52 lb. She had been passing four to eight watery stools daily; the parents had not detected blood in them. She had suffered from weakness and loss of weight for three months. She was acutely ill and emaciated, with a temperature of 101.4°F. There was a marked pallor of the mucosa of the lips; the conjunctiva was bluish white and the palms and soles were waxy yellow. The heart, liver and spleen were enlarged. Examination of the blood revealed a haemoglobin value of 30 per cent. (Sahli), 2,300,000 erythrocytes per cmm and 3 per cent of eosinophils but no malaria. Examination of the stools revealed *Entamoeba histolytica* and eggs of *Trichuris trichiura*, *Ascaris lumbricoides* hookworm and larvae of *Strongyloides stercoralis*. The patient was treated with emetine hydrochloride for three successive days and then with oil of chenopodium but died on the fifth day. Autopsy confirmed the points mentioned above. In the small intestine there were a few *Trichuris* and six *uncinarias*. From the caecum downwards throughout the whole large intestine and including the appendix there were more than 1,100 specimens of *Trichuris* and a number of others were lost. The mucosa of the large intestine and caecum was injected and covered with mucus in which *E. histolytica* was found. There was dilatation of the heart, pulmonary oedema, fatty liver and secondary anaemia.

The second subject was a mestizo boy aged four years weighing 24 lb. He had had bloody diarrhoea, fever and cough for three days. He also was acutely ill showing signs and symptoms essentially similar to those shown by the first subject. The rectal mucosa was prolapsed and several specimens of *Trichuris* were seen moving about on the prolapsed tissue. This is not uncommon in Panama children. Examination of the blood of this subject revealed a haemoglobin value of 30 per cent. (Sahli), 2,300,000 erythrocytes per cmm and 4 per cent of eosinophils but no malaria parasites. In the stools the eggs of *T. trichiura* and *Ascaris lumbricoides* were found. The boy died 23 hours after admission to hospital. Autopsy revealed near the ileo-caecal valve one *A. lumbricoides* and a number of *T. trichiura*. In the caecum and ascending colon there were eight masses of *T. trichiura* numbering more than 1,700 altogether. No amoebae were found. There were small ulcers in the lower sigmoid and rectum. There was dilatation of the heart, enteritis, colitis, secondary anaemia and emaciation.

The third subject was a mestizo girl aged 7 years, weighing 24 lb. She had had diarrhoea for six weeks, with fever and swelling of the face for five days. She was emaciated and could not stand. She showed the same external evidences of secondary anaemia as the two previous subjects, and in addition oedema of the face, hands, abdomen and lower extremities. Examination of the blood revealed a haemoglobin value of 30 per cent. (Sahli) 2 400 000 erythrocytes per cmm. 3 per cent. of eosinophils, but no malaria parasites. The Kahn and tuberculin tests were negative. The stools contained eggs of *T. trichiura* *Necator americanus* *Ascaris lumbricoides* but no *Entamoeba histolytica*. Blood transfusions and a course of hexylresorcinol failed to prevent her death 19 days after admission to hospital. Autopsy revealed 140 uncinae in the small intestine between the caecum and the anus 4 100 *T. trichiura* were counted. Some of these were in six or eight masses they also occurred in the appendix. There was secondary anaemia, acute cardiac dilatation pulmonary oedema and fatty changes in the liver and myocardium.

The fourth subject was a mestizo girl, aged 7 years weighing 40 lb. She had had shortness of breath swelling of the face and hands and dark red urine. She was emaciated and sunk in deep coma with a temperature of 101°F. She had oedema of the face, hands, abdomen and lower extremities. Examination of the blood revealed a haemoglobin value of 30 per cent. (Sahli) 2,300 000 erythrocytes per cmm. 4 per cent. of eosinophils but no malaria parasites. The Kahn test was negative. The stools contained eggs of *T. trichiura* but no *E. histolytica*. The patient died in 30 hours. Autopsy revealed that the primary cause of death was acute haemorrhagic nephritis. It also revealed pericardial effusion a dilated heart and about 250 cc. of fluid in the peritoneal cavity. In the large intestine more than 400 specimens of *T. trichiura* were counted, but there was no ulceration. Like the other three she had secondary anaemia. The author concluded that although the first patient harboured five species of parasite, the infestations with *Strongyloides* and *Ascaris* were mild, because they were not found at autopsy after five days in hospital. The *Necator* infestation in this patient was also probably mild. *E. histolytica* may have been important but the *Trichuris* infestation was the predominant feature. In the third the *Necator* infestation may have been a contributory cause of death. In the second the *Ascaris* infestation was not significant. In the fourth the haemorrhagic nephritis was the primary cause of death, but this subject was the only one of the four who harboured *Trichuris* only and this must have debilitated the child. The first three illustrate well the view expressed by CRAIG and FAUST (*Clinical Parasitology* 3rd edn. 1943 p. 241) that clinically heavy infestations with *Trichuris* may suggest severe hookworm disease. The most important signs of severe *Trichuris* infestation are diarrhoea, blood-streaked stools, weakness and loss of weight, with pallor, fever, emaciation, anaemia and abdominal distension. The autopsies showed that the *Trichurids* may invade the whole length of the large intestine but that there may be no characteristic lesions. Gets has examined subjects with the proctoscope and has found that the whole wall of the lower part of the descending colon and of the sigmoid may be covered with an almost continuous film of living moving trichurids. Infestation with *Trichuris* is however usually considered to produce only mild clinical effects (the author refers, for example to FERNÁN NÚÑEZ this *Bulletin* 1927 v 24 1002). These four subjects show that its effects can be severe, and in his survey of the literature, the author refers to other instances. It seems certain that the prolonged diarrhoea and anaemia may result in cardiac failure and death, but we still do not know how *Trichuris* causes anaemia.

DEFICIENCY DISEASES

GILLMAN T & GILLMAN J Powdered Stomach in Treatment of Fatty Liver and other Manifestations of Infantile Pellagra Its Significance with reference to the Problems of Edema and Steatorrhea in Infants and in Adults. *Arch Intern Med* 1945 Aug v 76 No 2 63-74 [Refs in footnotes]

In this paper the authors amplify their views as to the aetiology and pathology of infantile pellagra in Africans seen in Johannesburg and record the continuing success of treatment with a preparation of powdered stomach. In previous papers [this *Bulletin* 1944 v 41 1057 1945 v 42 748] they reported rapid cure in each of six cases treated in this way together with administration of a good diet they now record three more patients in whom the same satisfactory result was achieved and they again mention the cases previously treated with vitamins or with liver preparations in whom the results were poor most of the patients dying. The chief clinical findings in these children were dermatitis (sometimes with exfoliation and ulceration) a smooth atrophic tongue cheilosis oedema of various degrees enlargement of the liver (due to accumulation of fat in the liver cells) microcytic anaemia reduction in serum protein especially albumin (but the oedema is not related to this) and the passage of bulky offensive stools containing a high proportion of fat.

As a result of their observations the authors conclude that the liver kidney and stomach are closely interrelated in the control of water metabolism one of the striking features of treatment with powdered stomach was the dramatic disappearance of the oedema. Another effect was the disappearance of the steatorrhea. The cause of steatorrhea in coeliac disease and sprue is not well understood but the suggestion is made that in infantile pellagra there is first a dietary deficiency and vitamin imbalance which leads to disturbance of fat metabolism that the continuous presence of fat in the alimentary tract leads to the formation of enterogastrone a hormone which inhibits gastric activity by suppression of the formation either of the intrinsic factor or of hydrochloric acid. Prolonged inhibition as in chronic sprue may eventually result in complete suppression of all the functional activities of the stomach. The thesis is advanced that though in the first place the dietary deficiency is responsible for initiating the changes of infantile pellagra they lead to secondary changes and that where these occur treatment by administration of vitamins is no longer capable of restoring the normal condition. Treatment with dried stomach corrects these secondary effects. A disease at a certain stage loses its connection with the initial cause. The subsequent course of the disease may then be determined by the secondary pathologic changes.

The dose of powdered stomach was 10 gm daily for five days.

[These findings are evidently of great importance in saving life. It may perhaps be permissible to emphasize the fact that this syndrome which reflects the bad state of nourishment of these unfortunate people is preventable by action to ensure an adequate diet.]

Charles Wilcocks

MEYERSBURG H A. Senile Psychosis and Pellagra. A Report of Two Cases. *New England J of Med* 1945 Aug 9 v 233 No 6 173-6 [28 refs.]

Senile psychosis may be simulated by pellagrous encephalopathy in the aged. The underlying neurologic alterations in the elderly patient may predispose to this occurrence.

The senile-pellagrous type of encephalopathy may respond well to treatment with crystalline vitamin B products or with natural vitamin B concentrates. The recognition of this group of cases may permit effective therapy.

The maintenance of an optimal dietary by the normal aged person as well as by the senile invalid should be a matter of primary importance."

SPIES T D PERRY D J., COGSWELL, R. C & FROMMEYER, W. B. Ocular Disturbances in Riboflavin Deficiency *J Lab & Clin Med* 1945 Sept., v 30 No 9 731-65 6 figs. & 4 coloured figs. on 1 pl. [20 refs.]

From among patients attending the Nutrition Clinic of the Hillman Hospital, 500 were arbitrarily selected for treatment of these, 300 treated by at least one intravenous injection of riboflavin form the subject of this article. They were all persons who had developed ocular disease after subsisting on diets judged to be deficient in riboflavin were aged between 8 and 92 years, male and female, both white and negro. The majority were selected as having no organic disease no clinical evidence of co-existing deficiency disease and no known disease of the alimentary tract.

The subjects were for the most part treated as out patients and were observed before during and after treatment. In many cases slit lamp examinations were made bacteriological investigations were carried out in 50 cases riboflavin blood levels determined in 50 and urinary levels in 50 by the microbiological method. Dietary studies were made from data supplied by the patients and these in general, suggested a 64 per cent deficiency of riboflavin intake. The common complaints were nervousness insomnia, headache burning and aching of the legs and feet, burning and cramping of the stomach, constipation burning of the skin itching and burning of the eyes and falling vision, symptoms which waxed and waned in intensity 154 had cheilosis [angular stomatitis] at some time on one side only in 15 but none had the abnormal redness of the lips [cheilosis] in 2 the tongue was magenta red in 12 the naso-labial folds were affected.

Conjunctivitis both bulbar and palpebral, was sometimes the sole manifestation. In all 300 "it was observed that small vessels encroached on the cornea at the scleral corneal junction [not further defined] Circumcorneal injection was grossly visible in 80 per cent. interstitial [sic] keratitis was present in 60 per cent. and corneal ulceration in 53 per cent. pterygia was noted in 50 per cent.

The case notes of three subjects are given at length.

[This article contains nothing essentially new its chief value lies perhaps in the fact that the authors have come to recognize as others have done how great is the uncertainty concerning riboflavin and deficiency disease. They say—"We freely admit that we do not know what specific ocular symptoms and lesions are caused by riboflavin deficiency After stating that 'It is only by determining the effect of riboflavin therapy on the ocular manifestations that a diagnosis of riboflavin deficiency can be made the authors add—"that this method of diagnosis and treatment is unsatisfactory we know In regard to the symptoms described, they say— It is to be admitted freely that the picture described is not one which is pathognomonic of riboflavin deficiency or one that can be immediately and specifically differentiated from superficial inflammation of the eye from numerous other causes. Again "this therapeutic test may in itself not be thoroughly valid because we have gained an impression that most inflammatory disorders of the superficial portions of the eye may be benefited to some degree by an excess of riboflavin to the organism. "All our studies on the riboflavin content of the blood tend to indicate that there is little or no fall in the concentration of riboflavin even in the presence of severe lesions." In fact, anyone about to write upon

the subject would do well to remember the authors final conclusion— we must admit at this time riboflavin deficiency is little understood.]

HAEMATOLOGY

PONDER E. The Sickling Phenomenon and its Bearing on the Problem of Red Cell Structure *J Exper Biol* 1945 Aug v 21 Nos. 3 & 4 77-83
1 fig [30 refs.]

For the purpose of description the author calls an erythrocyte which appears normal but which under suitable conditions becomes a sickle cell a promenisococyte. In vaseline-sealed cover glass preparation the plasticity of the promenisococyte becomes increased after a period of time which varies with the thickness of the preparation the temperature and other factors. The rim of the cell becomes progressively thinner on one side until usually within one to two minutes continuity breaks down. The crescent so formed then opens out rapidly within about a second and the thin stretched concave edge expands into a series of veil like projections. At the same time the total length of the crescent contracts but the mean cell thickness increases and the volume does not change. After some hours or days the cell rounds up becomes a polytic sphere and is haemolysed. As the crescent opens up one or more slender filaments arise from each point 10μ or more in length and shorter filaments may extend outwards from the scalloped concave edge of the crescent. If the sickle cell is retransformed into the discoid form the long filaments break off at their bases and contract into rods or globules which can be seen floating freely in the plasma. Sometimes the rim of the promenisococyte thus irregularly giving rise to very bizarre forms of cell.

Oxygenation of a sickle cell results in lengthening of the crescent with increase of its curvature while at the same time the concave border extends further and becomes smoother until finally the points of the arc meet and the discoid form is re-established. At the junction of the points of the arc a small globule is formed and occasionally the filaments remain tangentially attached to the cell at this point for some time. Reversal of a sickle cell to discoid form under suitable conditions usually takes some minutes. A cell sickling for the second time does not necessarily break at the region of the previous junction.

Sickle cells undergo no sudden changes of shape on the addition of rose bengal lecithin or saponin. They remain as sickles until the time of lysis when they turn into spheres or fade from view unlike normal cells which before haemolysis become spherocytic under the action of the first two agents and crenated by the last. The ghosts of sickle cells so obtained are however never sickle-shaped but always irregularly spherical while ghosts obtained by lysing sickle cells with water are discoidal in conformity with the rule that mammalian water ghosts are biconcave discs although they often show considerable crenation. Exposure of meniscocytic ghosts to low oxygen tension does not result in any change in shape of the sickling type since the presence of haemoglobin in the cell is necessary for the transformation from discoid to sickle shape.

The shape of erythrocytes is probably determined by a balance of forces. The force of surface tension tends to produce a spherical form while it is suggested the forces which maintain the cell as a biconcave disc are repulsions

between the side chains of radially arranged cephalin molecules. To account for the sickle-cell process it is necessary to suppose that the haemoglobin in the cell exerts an "expansive force" a function of the oxygen tension. In the normal cell this force produces only tension, but in the promelasocyte, owing to some defect in the ultrastructure [presumably the molecular structure] of the envelope it produces sickling. It is suggested that the inability of the ghost cell to form spheres is due to the disappearance of the forces associated with the haemoglobin while the forces of surface tension become equal both inside and outside the ultrastructure. Leptoscopic measurements have shown the normal red cell envelope thicker by some 30 to 50 Å in the region of the biconcavities than elsewhere and that this difference is increased by organic solvents. The question now arises whether haemoglobin is distributed uniformly throughout the cell, either as a highly viscous solution or as a gel, for it becomes absent from the veil like material of the sickle cell, a material which corresponds to that of the biconcavity of the normal disk. It may be that during sickling the surfaces of the ultrastructure in the region of the biconcavity come into apposition and so drive the pigment into the body of the memasocyte: this explanation retains the idea that the haemoglobin is in solution. An alternative type of explanation is that the pigment is not in solution, but is combined or imbedded in a cytoplasmic matrix and that it leaves the region of the biconcavity by a process similar to that of protoplasmic streaming.

DERMATOLOGY AND FUNGUS DISEASES.

FOXZARI M. Algumas causas desencadeantes do pénfigo foliáceo [Causes precipitating (the Onset of) *Pemphigus foliaceus*] *Brasil Medico* 1945 July 21 & 23, v. 59 Nos. 29/30 261-4 4 figs. English summary

Some authorities regard *Pemphigus foliaceus* as an allergic manifestation, or as the author calls it, pathergic, by which term we are to understand that some agent as it were pulls the trigger and sets the disease going. Such a precipitating agent may be a streptococcus or a mosquito-bite for example. The history of one case was as follows. A man of 23 working as a woodcutter complained of difficulty in swallowing for 10 days or so. He was then bitten by a mosquito on an eyelid. A bulla formed, followed by others in various parts of the body. Acute pemphigus ensued and death occurred five days after his admission to hospital. Another referred the onset of his attack to being bitten by ticks while he was working in a wood: this resulted first in itching and burning and later in bullous formations and pemphigus. In yet another case the origin of the disease was definitely associated by the patient with his having scalded his foot and hand with some fat some three months before. Bullae broke out, burst and healed with scarring. Then other bullae appeared in other parts of his body which ulcerated and a condition of pemphigus set in and death took place soon after his admission to hospital.

The author accounts for the failure of sulphonamides and penicillin to cure—and he quotes half a dozen cases in which penicillin was administered in doses ranging from 100,000 to over a million units—by saying that, though the secondary or concomitant infection might be overcome the pemphigus continued on its way unchecked.

BUTT E M & HOFFMAN A M Healed or Arrested Pulmonary Coccidioidomycosis. Correlation of Coccidioidin Skin Tests with Autopsy Findings *Amer J Path* 1945 May v 21 No 3 485-505 12 figs on 5 pls. [10 refs.]

The correlation of the coccidioidin dermal reaction with coccidioidomycosis and calcified pulmonary nodules has been discussed by many writers and this literature is summarized in a paper by COCK and SMITH (*Arch Pathology* 1939 v 27 717-34)

The present work deals with the post mortem pathological study of patients on whom the coccidioidin test had been made. The Santa Fé Coast Lines Hospital in which the study was made receives patients from a wide area which includes most of the known endemic areas of coccidioidomycosis. As the patients are members of the Hospital Association they return regularly and may be kept under observation for a long time (in some cases for 25 to 30 years) and eventually an autopsy may be obtained. Of 1 165 patients tested with coccidioidin 302 (25.9 per cent) gave positive reactions. The incidence of positive reactors amongst patients from the major endemic areas was from the San Joaquin Valley 82.8 per cent, Arizona 28.0 per cent, and Texas 35.7 per cent.

Autopsy was made on 36 patients of whom 11 had been reactors to coccidioidin. Nearly all of these 11 showed pulmonary calcareous or fibrous nodules and parasitic spherules were found in the healed lesions of eight but in only five could the spherules be identified with certainty as *Coccidioides immitis*. In none of these positive reactors was a clear clinical history suggestive of coccidioidal disease obtained. Of the 25 patients negative to coccidioidin, all but four had calcified nodules in the lung but in only one of these were (very dubious) spherules found.

The calcified lesions of coccidioidomycosis are indistinguishable grossly from similar lesions of tuberculosis except that apical scars are not found in uncomplicated healed or arrested pulmonary coccidioidal disease. Inoculation of material from some of the cases into guineapigs and attempts at culture suggest that most of the lesions are mycologically and bacteriologically sterile.

As with the tuberculin test and tuberculosis there seems to be a rough quantitative relationship between the coccidioidin skin reaction and the activity or age of the primary coccidioidal lesions. The coccidioidin reaction may be negative in advanced and progressive coccidioidomycosis and it is probable that it may become negative in some patients with healed lesions. There is apparently no cross-allergic relationship of tuberculin and coccidioidin and no cross-relationship between the coccidioidin test and similar tests with the allergens of *Blastomyces Aspergillus* or *Sporotrichum* J T Duncan

MOSTO D & IARICCI V Presentación de un caso de granuloma por *Paracoccidioides brasiliensis* [Description of a Case of Granuloma caused by *Paracoccidioides brasiliensis*] *Rev Asoc. Med Argentina* 1945 July 30 v 59 No 562 828-30 11 figs.

Paracoccidioidal granuloma was formerly mistaken for the coccidioidal granuloma of Posadas-Wernicke but DE ALMEIDA in 1930 showed that the parasitic spherules of the causative fungus differed from those of *Coccidioides*

sporidia in having no internal spores, but instead an external surrounding zone of small spore-like reproductive bodies. The fungus was therefore placed in a new genus *Paracoccidioides* Almeida 1930 as *Paracoccidioides brasiliensis* (Splendore) Almeida 1930. The disease called paracoccidioides granuloma, is regarded as clinically more closely related to Gilchrist's disease or North American blastomycosis than to coccidioidomycosis. The authors describe four cases of paracoccidioides granuloma in Argentina, three of which had been published previously. In two of these three there was extensive involvement of the lungs, with cavitation in one case, and in both there were ulcerating granulomatous lesions in the mouth. In the third case there was extensive disease simulating carcinoma of the head of the pancreas extending to adjacent abdominal viscera. In all cases there was localized adenopathy with caseation and suppuration in some of the glands. The diagnosis was based on histological examination of tissue obtained by biopsy which showed the characteristic granuloma composed of great numbers of multinucleated giant cells and histiocytes containing the parasite (a thick walled spherical body varying in size from 1 to 30 μ surrounded by a zone of small bud-like bodies) plasma cells lymphocytes and eosinophiles. Suppuration was associated with a fibrinoleucocytic exudation which, the authors believe is provoked by a secondary bacterial invasion. In one case the diagnosis was confirmed by inoculating the sputum into the testis of a guinea pig with reproduction of the disease and in the other two by post-mortem examination. Tuberculosis was excluded in all cases. In the fourth case hitherto unpublished, the lungs were involved and there were associated granulomatous ulcerating lesions in the mouth with adenopathy of related lymphatic glands. The ulcers in the mouth were covered with a whitish exudate suggesting leucoplakia and were painful and bled on contact. The patient suffered from loss of weight and anorexia with a febrile condition increasing with the progress of the disease.

Paracoccidioides granuloma has only recently been found in Argentina and involvement of the lungs is believed to be comparatively rare occurring in only about 15 per cent. of the cases as compared with 95 per cent. in coccidioides granuloma.

HEAT STROKE AND ALLIED CONDITIONS

PARK, R. G. Disorders due to Heat. *New Zealand Med J* 1945 June v 44 No 241 128-31

One of the objects of this paper says the author is to pass on some practical points learnt in four years of tropical military medicine. He first discusses hyperpyrexia, when he emphasizes that the primary disorder is a failure of the sweat glands. In the dry heat of North Africa little hyperpyrexia was seen [but in the hotter Arabian desert WATERLOW HUDSON and LADKILL did encounter such cases]. Hyperpyrexia must not be confused with cerebral malaria. After excessive sweating there may be a heat exhaustion there is here peripheral circulatory failure and the general picture of shock. The author outlines the nervous and humoral control of the sweat glands and the effect of drugs upon sweating. He then describes the clinical effects of hyperhidrosis of which the most important is heat cramp their diagnosis and treatment. [There is some confusion in this paper between pathological hyperhidrosis and the high sweat rates that occur naturally in extreme heat for the former the author recommends X rays sympathectomy or belladonna.

Administration of water and salt is advised as treatment of the effects of excessive sweating but the importance of water and salt as a prophylactic against these effects is not emphasized.]

For prickly heat a calamine lotion is recommended. Hot climates aggravate sweaty feet but infection is equally important and the condition may be constitutional. Some relief may be obtained by avoiding heavy boots or rubber shoes. Skin hardeners such as spirit or formalin prevent maceration and infection a powder containing salicylic acid should be used after drying the feet. A cream containing hexamine which when wetted with sweat from the feet released formalin, is useful in mild cases. The relief given by X rays is usually only transient.

MISCELLANEOUS DISEASES

PAVLOVSKY E N Natural Focal Localization of Human Transmissible Diseases and the Concept of Landscape as an Epidemiological Factor *Med Parasit & Parasitic Dis* Moscow 1944 v 13 No 6 29-38. [In Russian.]

In the course of numerous parasitological surveys throughout the Soviet Union by expeditions led or organized by the author observations were made on certain peculiarities in the distribution of some transmissible diseases which are of epidemiological importance. Some of these diseases manifest a natural focal localization within well-defined geographical areas (biotopes) where the pathogenic organisms their vectors and hosts form an ecological association (biocoenosis) enabling the infection to circulate for indefinite periods of time from donor-host via vector to recipient host. One of the characteristics of such a focus of infection is its complete independence of man (and domestic animals). However human beings temporarily entering such a locality expose themselves to bites of the vector and may become infected. Furthermore if man settles down to live in a zone where such foci exist one of the following relations will be established between him and the focus (a) The focus might prevail over man giving rise to outbreaks of the disease (b) the economic activities of man might bring about the extinction of the focus or (c) the focus might continue to exist in proximity to but not in contact with man with the result that it remains potentially dangerous.

This type of focal localization has already been discovered for a number of diseases. Thus in the desert areas of Central Asia, oriental sore occurs naturally among gerbils which share their burrows with the sandfly vector. This disease is a typical zoonosis being transmissible to human beings when these come into contact with sandflies infected from the rodents which represent the reservoir host [see this *Bulletin* 1944 v 41 331]. Similarly the foci of spring-summer encephalitis are found in uninhabited forest areas of eastern Asia, where the infection is maintained in various wild animals and in the tick vector. When bitten by ticks human beings become infected the result of the infection differing according to the dose of virus received if this was large the infection develops all the symptoms of encephalitis if it was small active immunity is acquired. Focal localization also occurs in various tick borne typhus fevers (tsutsugamushi, Rocky Mountain fever and similar diseases in the Soviet Union). One of the expeditions led by the author discovered in the steppe zone of the Krasnoyarsk territory (Siberia) natural foci of typhus fever affecting wild rodents (marmots, field mice and hamsters) and transmitted by ticks (*Dermacentor nuttalli*). Like other zoonoses this disease

is maintained independently of man who becomes infected accidentally when attacked by the vector. Among other diseases with a natural focal localization independent of the human host the author mentions plague, tick borne relapsing fever, tularaemia, Japanese encephalitis, yellow fever, brucellosis, rabies, probably kala-azar and sandfly fever and possibly also various typhus fevers (both louse- and tick borne).

The natural foci of transmissible diseases can remain undetected and dormant for indefinite periods of time as long as human beings do not come into contact with them. They therefore constitute a potential epidemiological danger and it is important that their existence should be recognized beforehand. Since such foci are characterized by definite geographical peculiarities which can serve as indicators of the presence of certain diseases in such areas a knowledge of what is termed the landscape epidemiology is useful in determining the potential danger of places about to be occupied by man. Thus the tundra zone of Siberia is the habitat of numerous blood-sucking Diptera and may harbour foci of tularaemia. The forests (taiga) of the Far East represent the endemic zone of tick-borne encephalitis while tick borne typhus fever occurs in the region of wooded plains of Siberia. On the other hand, the desert regions of Middle Asia contain the typical biotopes of oriental sore and tick borne relapsing fever.

C. A. Hoers

HODES, P. J. & WOOD, F. C. Eosinophilic Lung (Tropical Eosinophilia). *Amer J Med Sci* 1945 Sept. v 210 No 3 288-95 2 figs.

A helpful contribution in attempting to contrast fundamental differences between eosinophilic lung and Loeffler's syndrome. The authors give a brief sketch of the literature on the subject of eosinophilic lung and then describe two cases observed by themselves: one an Anglo-Indian from Calcutta, the other an Indian from Madras. Both had a little fever to 102° in the former to 101° F in the latter with leucocytosis 21,000 and 40,000 per cmm respectively and eosinophiles 38 and 65 per cent. soft mottled patches in the lungs and disappearance of symptoms on treatment with neosarsphenamine.

The differences between this and Loeffler's syndrome are given as absence of asthmatic attacks, more developed nodules seen in X-ray pictures, less degree of leucocytosis, transiency of lung conditions, more seasonal (especially prevailing in the summer months) and occurring in temperate climates as well as in the tropics and subtropics, all being characteristics of Loeffler's syndrome.

H. Harold Scott

LEE, R. K. C. & PANG, H. Q. Ichthyotoxism—Fish Poisoning. A Report and a Review. *Amer J Trop Med* 1945 May v 25 No 3 281-5

Of the two forms of fish poisoning that by toxins present in the living fish and that inserted by wounds inflicted by the spines, the present article deals with the former. Two outbreaks occurred in Honolulu in the last two months of 1944, the persons attacked numbering 34 and 14 respectively and all showed symptoms a few hours after ingestion of sea bass, *Paralichthys leuostictus* and *Serranus fasciatus*. The fish appeared to be quite fresh. Animals to whom some of the fish was given were also poisoned.

The symptoms in the human cases were much the same in all. They might set in within a couple of hours or be delayed for 6-7 hours. They started with diarrhoea and some abdominal pain (not severe), the stools were liquid, light in colour at first and frequent, every 10-15 minutes. An hour or two later there would ensue a numb sensation in the lips and mouth with aching of limbs, perhaps severe enough to need an opiate. At the same time there

was a burning sensation in the mouth making swallowing difficult and a feeling described as a dry ice sensation of the palms and soles. 48 hours later there was itching of the hands and feet, but no rash. The patients were sufficiently recovered to be able to get about in 10 days or so but on leaving hospital the paraesthesia or itching was still present. There was no fatal case so pathological lesions could not be studied.

Variola louti frequents the waters of Christmas Palmyra Wake Society Fanning and Apiang Islands and near the Red Sea the *Serranus fascogut* takes much the same area. Palmyra Ponape Gilbert Marshall Christmas Tonga Reva and Fanning Islands. Both species belong to the Sea Bass or Grouper family and go by the local names of Hapapu in Hawaii Shakepan among the Chinese and Ara among the Japanese. Whether the poison arises from substances on which the fish feed or on poisons developing at the spawning season is referred to as it usually is in other papers dealing with this subject but no definite conclusion is reached. SENEULT R. Observations on the Incidence of Cancer in Trinidad. *Caribbean Med J* 1945 v 7 Nos 2 & 3 72-84

GENERAL PROTOZOOLOGY

JOHNSON G TRUSSELL Margaret & JAHN Frances. Isolation of *Trichomonas vaginalis* with Penicillin. *Science* 1945 Aug 3 126-8 [Refs in footnotes]

The authors have worked out a technique for obtaining bacteria free cultures of *Trichomonas vaginalis*. To 10 cc. of C.P.L.M. medium (cysteine peptone liver infusion maltose and human serum) penicillin was added to a strength of 5 000 to 10 000 units per cc. To each tube was added two platinum loopfuls of vaginal discharge known to contain the flagellate. The tubes were then incubated for 60 hours at 37°C. At the end of this period transfer into the same medium without penicillin was carried out and further transfers were made every 40 to 44 hours. Bacteria free cultures were obtained in this way from seven consecutive cases. In the early cultures the flagellates showed a tendency to grow in clumps as did the first bacteria free cultures isolated by TRUSSELL in 1939 (*J Iowa State Med Soc* 1940 v 30 66). As in his case with repeated subculture the tendency to clumping was lost.

C M Henyon

HEATH P & ZUELZER W W. Toxoplasmosis. Report of Ocular Findings in Infant Twins. *Arch Ophthalmology* 1945 Mar v 33 No 3 184-91 5 figs. [15 refs]

Identical negro twins born prematurely at the eighth month were found to have been suffering from toxoplasmosis when a post mortem examination was made of one which died at the age of one month. The other was still alive at seven months. The infection which must have occurred not later than the seventh month of gestation had caused arrested development of the eyes in which destruction of the young nerve tissue causing bilateral choroidoretinitis was detected. The post-mortem findings in the eyes of the twin that died and the ophthalmoscopic appearances of the eyes of the survivor as observed from

time to time are described in detail in the paper which is a lengthy ophthalmological report on the cases. Sera from the surviving twin and the mother both contained neutralizing antibodies against toxoplasma as tested by Sabin's method.

GENERAL ENTOMOLOGY

WIGGLESWORTH, V. B. Transpiration through the Cuticle of Insects. *J. Exper. Biol.* 1945 Aug., v 21 Nos. 3 & 4 97-114 2 pls. & 6 text figs. [42 refs.]

The paper deals with the passage of water and other substances through the cuticle of insects, and with the lipid materials which in some cases greatly reduce the water loss. The work is reviewed here in general terms to indicate the contribution which the insect physiologist is making to the understanding of some of the problems of medical entomology. It is important to us in two ways. In the first place if the insect is to live in a relatively dry environment it must reduce the loss of water through its cuticle its power to do so will influence its geographical and seasonal distribution and, therefore the epidemiology of an infection which the insect transmits. But the subject is important also in a second direction in relation to the passage of the contact insecticides through the surface of the insect.

It is already known that the insect cuticle is a very complex structure. The impediment to the loss of water from the insect's body is generally ascribed to the epicuticle (which contains no chitin and is not penetrated by pore canals) more precisely the reduction of loss of water is thought to be due to certain waxy substances on or in the epicuticle.

Wigglesworth enters the subject by studying the loss of water from a number of insects which live in different habitats. He works generally with insects killed by cyanide at intervals and suspends them in dry air weighing them at intervals and he finds a striking contrast in the rate of loss of water in insects from different environments. For instance one beetle larva which normally lives in moist soil loses water at a rate approximately the same as that of an open water surface so that its cuticle offers almost no impediment to the outward passage of water. At the other end of the scale come insects with a very high resistance to desiccation and a much lower loss of water per unit area. It is also found that the rate of loss of water is a function of temperature though not directly so for in many insects there is a critical temperature above which the water loss is greatly increased. In such an insect as the cockroach this critical temperature occurs at about 30 to 35°C. so that the insect might find itself living either above or below the critical temperature. But in other insects which are more resistant to loss of water the critical temperature is above 50°C that is, above any temperature at which the insect can live.

The loss of water from the larva and pupa of the blowfly *Calliphora* is interesting. In the larva whether it is feeding or has emigrated from the meat, the critical temperature is about 35°C and in the young puparium it is approximately identical. But in the puparium a few days old the critical temperature is much higher and there is a much greater resistance to the loss of water. This increased resistance is not due to the thick outer skin of the puparium but to the very delicate cuticle of the pupa itself an indication of the importance of even the thinnest layer in reducing evaporation from the insect body.

Wigglesworth has also considered the effect of abrasive dusts on the wax films. It is already known that certain chemically inert mineral dusts are fatal to insects (indeed the method is used in destroying pests under certain circumstances) and that the cause of death is desiccation. In the present paper it is shown that this desiccating effect occurs only with the living insect and particularly if it moves about so as to rub some parts of its body on a surface which has been dusted. For instance the nymph of *Rhodnius* under certain atmospheric conditions loses about 2 per cent. of its weight in the twenty four hours. If it is walking on filter paper which has been covered with a mineral dust and dragging its abdomen over that surface the loss of weight may be increased ten or twenty fold depending on the nature of the dust. But if the underside of the abdomen is protected from contact with the dust the loss is only slightly greater than the normal. One may imitate this with the dead insect by rubbing parts of its body with abrasive substances. The fact that the abrasion actually removes the wax film is confirmed by dissecting off the cuticle and soaking it in ammoniated silver hydroxide. Where the wax film has been broken the underlying polyphenols are stained black, but there is no blackening where the film is intact. In this ingenious way it is shown that an abrasion occurs not only where the body drags over a surface but also at articulations and other points where body surfaces rub on one another. This is illustrated by microphotographs.

It is interesting to learn that breaches in the wax film are repaired and that this restores the impermeability to loss of water. This is associated with active changes in epidermal cells and emphasizes that insect cuticle is alive and that the control of loss of water is in no sense passive.

In a final section of the paper Wigglesworth describes experiments in which solvents and detergents are applied to the cuticle of various insects. His general conclusion is that the wax layer which overlies the epicuticle is further protected by a layer of cement. In the course of this work he was able to demonstrate that different types of detergents have different effects on the water proof layers of the cuticle and that this is reflected in the rate of entry of insecticides. For instance he secured capsules on the backs of nymphs of *Rhodnius* and in this way administered known doses of insecticides to known areas of cuticle. He found that nicotine in refined paraffin had almost no effect on the bug in two days but the same dose applied in the cetyl ether of polyethylene glycol killed all nymphs in twenty four hours. P. A. Buxton

ALPATOV V. V. NASTUKOVA O. K. & KHARTULARI 'E. M. [Eggs of the Head and Body Forms of *Pediculus humanus* L. and their Variation associated with Conditions of Rearing.] *Zoologicheskii Zhurnal* Moscow 1945 v 24 No 1 42-7 [In Russian.]

The exact status of the head and body forms of human lice (*Pediculus*) is not quite clear. Some workers have believed them to be separate species and others that they are merely modifications of a single species. A third opinion is that there is insufficient evidence to decide. An attempt to provide this evidence has been made by a biometric study of the eggs of the two forms.

CHOLODKOWSKY (*Zool. Anz.* Leipzig 1904 v 28 368-70 and *Vo. mod. Zh.* 1916 Nov-Dec.) first pointed out differences in the eggs of the two forms. TONKOVA however found differences as great between populations of each sort taken from different sources (*Izv. Akad. Nauk S.S.S.R.* [Bull. Acad. Sci. U.R.S.S.] 1927 v 21 397-404). The present authors measured six dimensions of the louse egg and took the position of the egg-cement as a seventh character. On the basis of these measurements mean figures with standard errors are given.

in tabular form from which it seems quite clear that the eggs of head and body forms are recognizably distinct (judged by averages) in natural populations.

Body lice and head lice from natural sources were reared in boxes worn close to the human body and fed thrice daily on the skin of the arm. It was found that the eggs of body lice remained unchanged, but that the head lice strain laid eggs identical with the body form within five generations. Even the first generation eggs were very greatly modified towards the body type. Similar results were obtained with lice kept in a thermostat at 30°C. No explanation can be offered for the change—it may be due to selection or by inheritance of acquired characters. Temperature is suggested as the factor which may be responsible.

The significance of the possible change of head to body lice is obvious when it is considered how much more common the head form is, being relatively common even among cultured people. If conditions of hygiene deteriorated the head lice might set up a general body louse infestation, which would pave the way for a typhus epidemic.

WEST INDIES. West India Royal Commission Report. [LORD MOYNE, STUBBS R. E., CROWDY Rachel E., CITRINE, W. MACKINNON P. G. BLACKLOCK, Mary G., ENGLENDOW F. L. & HENDERSON H. D.] Cmd. 6607 pp. xvii+480 1 folding map & 16 pls. 1945. June. London H.M. Stationery Office [7s. 6d.]

— West India Royal Commission 1838-39 Statement of Action taken on the Recommendations. Cmd. 6856 108 pp. 1945 June. London H.M. Stationery Office. [2s.]

— Development and Welfare in the West Indies, 1943-44. [STOCKDALE, Frank, K.C.M.G., C.B.E. (Comptroller for Development and Welfare in the West Indies). Colonial No. 189 pp. iv+115 1945 London H.M. Stationery Office. [2s.]

This report (Cmd. 6607) makes gloomy reading. It gives an account of the West Indies from the time when slavery was established, through the period of emancipation and the 19th century when the economic situation was grossly affected by the changes in world demand for the produce of the islands, to the position which existed immediately before the war. This position was bad, as was acknowledged by most of those competent to judge. Economically the islands were poor—their produce did not bring in revenue sufficient to maintain the people at a satisfactory level of subsistence—there was growing competition abroad—the islanders largely of African origin, had lost their old tribal organizations and standards, and these had not been replaced by any new cohesive structure of society which would tend to satisfactory community life or individual dignity. The people relied for subsistence chiefly on the sale of their labour and this was wanted at the cheapest rates and was needed, under the régime of 19th century economics, only in accordance with the fluctuations of general prosperity. Part time labour of the cheapest kind was the general rule existence being supported by the small holdings which a number of the people cultivated. The result was poverty, disease and waste of natural resources by inefficient farming set in a background of ignorance and superstition. Yet the population has not ceased to increase with consequent intensification of economic stress.

The diseases prevalent in these populations are those which would be expected in such circumstances. Malnutrition is general bowel diseases helminthiasis malaria, tuberculosis leprosy yaws and venereal diseases are the great problems. The arrangements for dealing with epidemics are fairly satisfactory and no doubt the protection afforded in this matter has prevented a heavier disease incidence and mortality than has actually been experienced. Expenditure on medical services during three years before the war varied from 8.9 to 19.6 per cent. of the total expenditure of the different countries and islands the average proportion spent on medical services therefore has been reasonably in line with the proportions so spent in other countries. But the Commission comment unfavourably on the general tendency to spend too small a proportion on preventive measures and too great a proportion (but not of course too great an actual amount) on the curative services. They argue that since most of the ill-health of these Colonies is due to preventable disease a greater proportion of medical effort should be devoted to prevention with its possibility of long term benefit than has so far been the case. They admit however the difficulty a Director of Medical Services must have in diverting part of his limited funds from the improvement of the curative services since pressure of public opinion is usually directed to means for the care of the sick and the curative services themselves badly need extension. The Commission also comment that the reason why preventive measures are not more cultivated is partly that the education and experience of members of the medical staff have been directed chiefly to curative work and that some of them lack the preventive outlook and partly that there is opposition by vested interests such as the owners of house property to needed preventive measures. The Commission condemn the view sometimes expressed, that it is useless to provide the people with good houses because they would convert the best of dwellings to the kind of slums they now inhabit. [To the reviewer this ignorant and thoughtless opinion (which usually is no more than a crude rationalization) is a social evil. The extreme examples of the concentration camps of Germany indicate that if men are treated like animals they tend to act like animals. The reverse that good environment tends to produce desirable persons is the basis of all social and educational work.]

Compared with some tropical countries the West Indies are fairly well supplied with Government doctors and with beds in Government hospitals but the needs are not by any means fully met so that more staff and more hospitals and other curative services are still demanded. There are many private practitioners but their position is not easy.

The Commission made certain recommendations for the appointment of a Medical Adviser for the whole area for the unification of the medical services for the centralization of the medical institutions for the creation of a school of hygiene for the development of long term health policies for the reorganization of the medical services and for an increase in certain preventive measures. Action was taken on these recommendations and on the general recommendations relating to other than medical matters the details may be found in the Statement of Action Taken (Cmd. 6656) which was presented to Parliament in June 1945. The Report of Sir Frank Stockdale (Colonial No 189) also describes the improvements which have been effected during 1943-44 even under the difficult conditions of war time.

To the reviewer it seems that hitherto the dominating force which has controlled the welfare of these people has been the commercial attitude. When trade was good they were comfortable and when it was bad they were almost destitute but all the time trade was the deciding factor and all the time the people were ignorant. The medical view of life is different. Medicine is concerned with human welfare not because men are units of production but

because they are human beings having the right to good health. It is no longer a principle of British government that colonies should be developed solely for the benefit of Britain or of big commercial interests, and the principle has been accepted that Native welfare is paramount. This being so and good health both physical and mental, being so cardinal a factor in human welfare, it seems evident that in the future the medical services should be given much greater prominence than ever before in the formulation of general political and industrial policies, and that the criterion which should determine action should be the needs of the people rather than their immediate capacity to produce. It is not, of course, denied that the capacity to produce is important, but medicine argues that one of the vital factors in efficient production is good health and that the rest depends, within the limits of what is possible in the countries concerned, upon organization and education.

There are indications in these reports that the importance of Native welfare is seriously accepted as the leading principle of government.

Charles Wilcocks

WEST INDIES. West India Royal Commission. Report on Agriculture, Fisheries, Forestry and Veterinary Matters [ENGLEDOW F. L. C.M.G. (Drapers Professor of Agriculture, Cambridge University)] Cmd. 6608. pp viii+235 1945 June. London H.M. Stationery Office. [3s. 6d.]

This Report, which surveys the agricultural resources and needs of the West Indian Colonies, and discusses local problems of livestock and fishery developments is supplementary to that of the West Indian Royal Commission (see above Cmd. 6607) of which Professor F. L. Engledow was a member.

INDIA. Annual Report of the Public Health Commissioner with the Government of India for 1941 and 1942 [COTTEK, E.] 63 pp 1 folding map 1944 Delhi Manager of Publications. [Annas 12 or 1s.]

Owing to war conditions this Report though it deals with two years of work, is less than half the size of the former annual reports. The mass of statistical matter that has been excluded will be published later.

Deaths from the diseases for which reasonably accurate statistics are available were —

	1941	1942	Average for 1936-1940
Cholera	228 141	218 496	135 723
Smallpox	59,307	27 137	64,088
Plague	11 984	10,577	20,923

Figures for deaths from malaria cannot be given, they form an unknown part of the total number of deaths from fevers of every kind, and diseases other than fevers are often included under this heading. The only areas in which malaria was exceptionally prevalent were the Punjab, Delhi Province and the North West Frontier Province in which epidemic conditions occurred in 1942. The epidemic in the Punjab followed a period of heavy rainfall in July and August so that the Annual Forecast was able to give timely warning, as a result of which arrangements were made in advance for dealing with the epidemic. The attendances at dispensaries in the Punjab during the year were more than two million. In normal years they were less than one million. The deaths from "fevers" in the province rose from 523,633 in 1941 to 604,295 in 1942, and presumably the increase was due to malaria.

The number of births in India in 1941 was 9 425 671 the deaths were almost exactly three million fewer the per mille figures were 32.1 and 21.8 respectively. In 1942 the births fell to 8 714,555 and the deaths to 6,336,313 the per-mille figures were 29.4 and 21.3. As the birth rate in India had remained steady at about 34 per mille for a number of years the progressive fall since 1930 is regarded as of particular interest in view of the world-wide discussions on what is regarded as the increasing population pressure in India and the alleged failure of food supplies to keep pace with it. [This remark seems to indicate that the author did not take a pessimistic view of the food situation but it would seem desirable to make a close investigation into the alleged failure because the allegation has been made by highly responsible persons, including a Member of the Viceroy's Executive Council. The Central Advisory Board of Health which held its fourth meeting in Calcutta in January 1942 did not discuss this problem and apart from one or two brief references to research on nutrition the report makes no reference to the subject of food shortage as a public health question. This omission is not really surprising because the prevention of disease caused by inadequate diet is usually regarded as being outside the scope of public health organizations.]

Inoculation against cholera has made rapid strides in recent years. In 1941 about 13 million persons were inoculated in the provinces of India, including nearly 3½ million in Bengal. In 1942 4½ million inoculations were carried out in Madras and more than 3½ million in Bengal.

Inoculation against plague was on a smaller scale. 600 000 persons were inoculated in 1941 mostly in Bombay Madras and the United Provinces. In 1942 the inoculations numbered less than 350 000 the reduction was chiefly in Bombay where less than 20 000 inoculations were carried out against 332,437 in 1941.

The incidence of enteric fevers in India is a matter of speculation even in the few areas in which the disease is a registrable cause of death the official figures give no indication of the real prevalence of the disease. [There is reason to believe that infection is so widespread that attacks in infancy and childhood confer a considerable degree of immunity on the adult population hence the absence of epidemics on a large scale.]

The tuberculosis situation is also somewhat obscure surveys were carried out in a number of localities and the Tuberculosis Association of India has continued to do active work in organizing research relief and teaching work in connexion with the disease. A model Tuberculosis Clinic was opened in New Delhi in 1941.

It is estimated that there are about one million lepers in India. Valuable work is being carried on by the India Council of the British Empire Leprosy Relief Association and by the Mission to Lepers which cares for 10 000 in 47 homes and hospitals and for 1 000 healthy children of lepers who are segregated from their parents. The total indoor accommodation for lepers in India is 13 676 beds.

The defects of the system of registration of causes of death are exemplified by the figures for kala azar in 1941. The deaths registered in Bengal were 16,349 in Bihar 91 and in Assam 40 whereas the cases treated in medical institutions were 105 018 in Bengal 119 465 in Bihar and 16 470 in Assam. It is suggested that the deaths from the disease in Bihar are probably registered under other causes.

The announcement by SWAMINATH SHORIT and ANDERSON in June 1942 [this *Bulletin* 1943 v 40 227] that kala azar had been transmitted to every one of six [five] volunteers by the bite of *Phlebotomus argentipes* is rightly described as a most important piece of work.

A brief account is given of the health activities of the Central and Provincial Public Health Departments. Five Health Units were operating in rural areas, each of which has a population of about 40 000 and the cost of each is about 30 000 rupees yearly. These units serve as demonstrations of the value of public-health services and as places of training for workers. The birth rates in two of them are stated in one it averaged 47.7 and in the other 48.9.

Famine conditions persisted in the Hissar District of the Punjab in 1941. Germinated gram was distributed to about 140 000 persons and although the amount was only a little over two ounces twice weekly a striking improvement in health is said to have resulted. In 1942 famine relief camps had to be opened in one district in Madras. During the two years measures for the relief of famine and scarcity were needed on a very small scale.

The provincial reports on health activities show that the war caused comparatively little interference. The report from Bengal contains no hint of premonition of the disastrous famine of 1943.

Maternity and child-welfare work obviously makes a special appeal to Indians. In Madras the expenditure on this by local bodies excluding Madras City was 560 000 rupees about four times as much as in 1932. No less than four voluntary organizations in Bombay were carrying out a co-ordinated effort directed chiefly to child welfare.

The subject of medical research is dealt with in separate reports, but it is stated that the most serious curtailment due to the war was in malaria research. High hopes are entertained that the destruction of adult mosquitoes by spraying will make widespread control practicable.

In addition to the voluntary bodies already mentioned, the Indian Red Cross and the St. John Ambulance Association continued their peace-time activities though most of their efforts were naturally directed to war work.

The Tuberculosis Association of India has opened a model Sanatorium at Kasauli and has considerably expanded its work of relief, propaganda, and the special training of medical men.

The Indian branch of the Ross Institute of Tropical Hygiene continued its valuable work of supplying expert advice and help to tea plantations and other industrial concerns.

[The production of this report in war time by the contemptibly small staff of the Public Health Commissioner's Office reflects great credit on Lt.-Col. CORRIE and his assistants.]

It is to be hoped that when Sir Joseph BHOZE has completed his comprehensive report on health conditions in India the governments and peoples of that country will realize the urgent need for planning and carrying out a campaign directed against all the causes of preventable disease. Hitherto the basic preventable disease malnutrition due to inadequate diet, has been practically excluded from the activities of public health departments except as a subject of research.

JOHN W. D. MCGEE

YACOB M. & SWAROOP S. Longevity and Old Age in the Punjab. [Abridged.] *Brit Med J* 1945 Sept. 29 433-6, 3 charts.

The authors discuss certain aspects of longevity in the Punjab and conclude that "the study indicates that one of the urgent needs is the making of reproduction an easy and risk free process."

The following statistics are of interest. In 1931 the expectation of life at birth in the Punjab was 28.05 years for males and 28.57 for females. For the whole of India the corresponding figures were 26.91 and 26.56.

During the five years 1935-39 the average infant mortality rates in the Punjab were 172 for males and 157 for females. Up to the age of 10

years the death rate among females was rather lower than among males but between the ages of 15 and 40 the deaths among females were considerably more numerous than among males—the rates were 30 for females and 24 for males

The authors comment on these figures is in England the rate of maternal mortality is as low as 2 or 3 for 1 000 births in the Punjab it is generally believed to be from eight to ten times this figure The absence of facilities for maternal relief and care coupled also perhaps with a rather unfavourable attitude towards the weaker sex in the Punjab are responsible for keeping female longevity at so low a level Female infanticide though no longer practised in the province is said to have persisted till comparatively recent times Sir James DOUGLAS is quoted as having stated in 1895 that fifty years after Lawrence denounced the murder of female infants we are still discussing the best method of putting down that inhuman practice

A graph is reproduced showing that from 1900 onwards the mortality rates among males and females have tended to decline

[No reference is made to the part played by the marriage of immature girls in causing the deplorably high rates of infant and maternal mortality in the Punjab as well as in the rest of India]

JOHN H. D. MORGAN.

WESTERN SAMOA The Twenty-Second Report on the Administration of the Mandated Territory of Western Samoa, covering the Four Years from 1st April, 1941, to 31st March, 1945 [FRASER P. Minister of Island Territories, 17 pp 1 chart 1945 Wellington New Zealand [6d]

The medical staff consists of three European medical officers 22 Native medical practitioners one European and four Native dental officers one European dispenser one bacteriologist (of part Samoan descent) 11 European matrons or sisters 95 Native nurses and 39 others The hospital at Apia has a laboratory and X ray department In 1944 there were 3 538 admissions to hospital and 69,839 out patients and 425 major operations were performed

The principal diseases are now —filariasis parasitic diseases (especially hookworm) typhoid pneumonia septic sores pulmonary tuberculosis. Cases of meningococcal meningitis and dengue were also reported in 1944 in considerable numbers Infectious jaundice (? leptospirosis) is also reported Infant mortality rates fluctuate considerably from year to year according to the reported figures it is not clear how comprehensive the reporting is but it is stated that in 1936 the heavy rate of 291.7 was due to epidemics of whooping cough and measles The rates in 1943 and 1944 were 124.4 and 75.8 respectively The total population as at March 31 1945 was 66 761 Charles WILCOCKS

COOK ISLANDS. Report of the Administration of the Government of the Cook Islands, including Niue for the Four Years ended 31st March, 1945 [FRASER P. Minister of Island Territories] 16 pp 1945 Wellington New Zealand. [6d]

The medical staff consists of two European medical officers and six Native medical practitioners four European sisters and 20 Native nurses one European dental officer and two Native dental assistants In 1944–45 for the population of 14,506 the health service expenditure was £12,724 representing 17s 6d per person For the same year in patients numbered 448 and out patients 8 603 and 101 major operations were performed

During four years there have been mild epidemics of influenza chickenpox measles and dysentery the most serious diseases are tuberculosis filariasis

and leptospirosis. Figures for these are not given. Infant mortality rates vary very greatly from year to year no doubt because the births registered are not numerous.

The health conditions of Lower Cook Islands and Northern Cook Islands are similar. At Nukunono there is a European medical officer, a Native medical practitioner, a European matron and three nurses. Of the infectious diseases, yaws appears to be the most prevalent, but filariasis is also common. typhoid has occurred. Infectious jaundice (? leptospirosis) caused 78 cases in 1944.

Charles Wilcocks

DEUTSCHMAN Z. Public Health and Medical Services in the Philippines.

Reprinted from *Far Eastern Quarterly* 1945 Feb 148-57 [12 refs.]

This short account of the medical services of the Philippines opens with a historical survey in which full justice is done to the extensive work carried out by the United States authorities until the inauguration of the Commonwealth, and to the efforts of the local administration after that date. During the present century the population has increased from 7½ millions to 16 millions, and during that period protection against the common epidemic diseases of the far east has been reasonably effective. Energetic administration has produced for these islands a more comprehensive system of medical care than exists in most countries of that region.

Immediately before the war the Bureau of Health included five divisions (Administration, Epidemiology, Hospitals and Dispensaries, Sanitation, and Maternity and Child Hygiene) and employed 690 doctors, 1,143 sanitary inspectors, 835 nurses, and other officials. There were 45 hospitals and 1,063 dispensaries, and certain clinics at which 281 physicians were employed. Campaigns for immunization and for construction of latrines (Almost two million of these had been made by 1938) were in being. The total number of hospitals in 1938 was 160 providing bed accommodation at the rate of 0.76 beds per 1,000 population (U.S.A. 9.7 per 1,000) there were 4,909 licensed physicians (1 for 3,216 of the population, a very high rate for the far east) and 5,030 registered nurses. The numbers of dentists, pharmacists and midwives were also large. There are four medical schools.

With the increasingly effective control of smallpox, cholera and plague (the last of which has not occurred since 1914) the health problems are more of the sub-tropical than the tropical type and the diseases concerned are tuberculosis ("the most important cause of death") malaria (a disease of the foot hills)

and nutritional diseases. Steps have been taken to deal with these but they are still serious problems.

Charles Wilcocks.

CORRYN E. N. The Pilgrimage to Mecca. Medical Care of Pilgrims from the Sudan. *Lancet* 1945 Oct. 6 445-6.

In this short but interesting note the author describes the medical mission which accompanied the Sudan pilgrims to Mecca in 1944. On their route from all parts of Africa the pilgrims pass through Suakim. In 1942 for the first time a Sudanese doctor himself a Moslem, accompanied the pilgrims to Mecca, and by 1944 the experience gained enabled the authorities to send a full mission consisting of two medical men, one medical assistant, one sanitary overseer and a hospital staff of seven (one a woman), one cook, one storekeeper and two ambulances with their drivers. A tented hospital of 30 beds was set up near Jedda and dispensaries at Mecca and Medina. Sudan pilgrims only were admitted as in-patients to the hospital, but out-patient treatment was given to all who desired it.

The venture was a great success and much use of these medical facilities was made by the pilgrims the total cost was about £5 000 Improved conditions in the camps at Suakin have added to the comfort of these travellers some of whom may be away from their homes elsewhere in Africa for two years before completing their journey

TEIXEIRA Q de A Fiscalização sanitária dos aeroportos. [Sanitary Control of Airports.] *Folha Med* 1945 Apr 25 May 5 & June 5 v 26 Nos 8 9 & 11 59-64 67-72 84-8.

This article may be regarded as a summary of lectures on aerodromes aeroplanes and the health of their crews and passengers, and the measures to be taken to avoid transmission of disease by vectors insect or human These lectures form part of a course on Public Health at the Oswaldo Cruz Institute Hence there is little here which lends itself to abstract since the whole is really devoted to pointing out the necessity for the rules which have been laid down and the dangers which would follow (and indeed have followed) neglect in carrying them out Tables are given recording the insects found, dead or alive in aeroplanes coming to Miami Florida in 1939 from Mexico Trinidad, Porto Rico Colombia Venezuela and elsewhere. The average incubation periods of various infectious diseases are given showing that all of them or practically all, are longer than most flights even long-distance and so stressing the importance of careful examination of crews and passengers and adherence to the regulations of the Pan American Bureau laid down in 1937 Disinfection of the aeroplane can be carried out during the flight by means of a spray containing pyrethrum and carbon tetrachloride in kerosene [DDT receives no mention] The regulations of the Argentine authorities for disinsectionization of aircraft (Jan. 1943) are quoted in full together with the apparatus to be carried and the details of procedure. The records for 1942 for the airports of Natal and Belém are given 457 planes were disinfected, 452 at Natal 5 at Belém, 4 194 arthropods were captured, of which 4 181 were harmless of the remaining 13 the chief was *Anopheles gambiae*

As regards passengers the author favours the issue of a Sanitary Passport which gives a great deal of personal information and calls for vaccination against yellow fever smallpox and enteric fever a Wassermann test blood examination for parasites search for intestinal parasites X ray of the chest bacteriological examination of the sputum, together with the identity card, place of residence for the week preceding embarkation and any history of recent contact with suspicious cases

H Harold Scott

NAPIER, L. E. *The Teaching of Tropical Medicine in the United States.* *Am J Trop Med* 1945 May v 25 No 3 233-40

The author begins by making the point that the teaching of tropical medicine as part of the general medical course for undergraduates has been neglected in the United States and in other countries. During the war medical men have served in the tropics and to equip them there have been instituted short courses of admittedly insufficient scope In the next few years moreover there must inevitably be the problem of the returned service man who will need in his own home the attention of local medical men for diseases with which they are not familiar Temporary arrangements have been made for the teaching of the present generation of undergraduates but these though probably the best under existing circumstances, are not ideal

The author's suggestion is that a broader teaching in systematic parasitology and tropical diseases (including nutritional diseases) should be integrated into the general medical curriculum, and that these subjects should not be

segregated from the rest of the course. The preventable nature of most tropical diseases should commend the teaching of them to the public health instructors. In this way the "purely artificial barrier that exists today between tropical and temperate medicine" would be broken down. The study of tropical diseases would contribute much to the general understanding of medicine.

For the training of medical men who propose to practise in the tropics special schools are needed, and these should be instituted in connexion with the large medical schools preferably those in seaports. For the United States three such schools are needed at first. A comprehensive syllabus is suggested, covering a course lasting 8 or 9 months, with about 1 000 hours of instruction.

Charles Wilcocks

MITCHELL, J. P. Medical Education in Uganda. *South African Med J* 1945 July 28, v 19 No. 14 242-5

The author traces the course of medical education in Uganda from the days when the epidemic of syphilis demanded the instruction of Natives in the simpler principles of diagnosis and treatment to the present time, when the Mulago medical school educates selected Africans, through a 6-year course to a stage at which they are competent to take charge of hospital and to perform major surgical operations. The details of the story need not be recounted here, but the author's conclusions drawn from his own long experience of these Africans during their training and after qualification, are important. He has no doubt of their capacity to do well the work for which they are trained, though he admits that for some time they will need guidance and that teaching and research will continue to demand the best European officers, but he is confident that the success of Mulago indicates that the same principles can be widely extended throughout Africa.

During the war we have had many distinguished medical visitors. All have expressed surprise that the African is capable of attaining the higher intellectual levels of the European. Only those who have worked for years with them appreciate that they can. Moreover I am frequently told that we are dealing with a more highly civilized African than is found elsewhere. We used to think so ourselves but we were mistaken. East Africans, other than the Baganda, have shown that given similar opportunities they can not only keep pace with the Baganda but outstrip them. And I would emphasize that they are the same people as I have seen all the way through Africa on journey south.

Mitchell pays tribute to the enthusiasm of those who have been selected from the European medical staff to carry out this training.

Charles Wilcocks.

JOHNSON, M. S. Rodent Control on Midway Islands. *U S Nav Med Bull* 1945 Aug. v 45 No 2 384-68

The Midway Islands (Sand Island and Eastern Island) in the North Pacific Ocean, have no native mammals but mice and rats have been recently introduced and have multiplied greatly. Rats were first noticed in March 1943; they have entirely destroyed two species of birds, the Laysan rail and the Laysan finch, have nearly exterminated the canaries and have no doubt reduced the numbers of other species of the island birds. They enter stores and other buildings but live mostly out of doors and commonly in the burrows of the Brown Island petrel, known as the "small moaning bird", whose eggs and young they eat.

So far only two species of rat have become established *Rattus rattus rattus* and *R. r. alexandrinus* the latter being three times as numerous as the former no part of the islands is free from them but they are most numerous in bush covered ground and here most of the petrel burrows are found

The use of poisoned bait seems to be the only effective method of control. Experiments with various kinds of bait and poison were made and are described in detail the poisons tried included squill Antu (3 per cent alpha naphthylthiourea) and zinc phosphide the last being the best. The aim is to cover the entire area of the islands by sections the minimal requirement being that each section should be baited for one month out of every three pans containing bait are placed about 100 feet apart (4 to the acre) and unpoisoned and poisoned bait are put in them alternately the former for 8-10 days and the latter for 3-4 days. The bait consists of maize meal 14 000 peanut butter 500 cottonseed (cooking) oil 350 brown sugar 500 and milk powder 250 parts respectively the poison is a mixture of zinc phosphide 2 parts and calcium carbonate 1 part and is added in such amount that the bait will contain 0.75 per cent of zinc phosphide.

In built up areas traps should also be used and buildings should be made rat proof. It is important to try to prevent the establishment of the Norway rat and to prevent the introduction of diseased rats and for this purpose poisoned bait and traps are used in the dock areas.

The results already obtained indicate that the rats could be much reduced in numbers but not exterminated by these methods. J. F. Corson

TANGANYIKA TERRITORY DAR ES SALAAM SURVEY DIVISION DEPARTMENT OF LANDS & MINES *Atlas of the Tanganyika Territory* With Foreword by H. P. ROWE (Chief Surveyor Director of Civil Aviation and Controller of Aerodromes) 29 pp 1942. Dec. [50s]

The Survey Division of the Department of Lands and Mines and those who collaborated with them are to be congratulated on an admirable feat of cartography in the production of this atlas. The features which it is desired to display in the various maps are very easily and clearly appreciated by the reader there is no fumbling in the drawing and the paper is of fine quality.

The maps (on 29 pages each measuring $17\frac{1}{2}$ in. \times $17\frac{1}{2}$ in.) show the physical features rainfall temperature etc. but for readers of this *Bulletin* particularly interesting are those which show the distribution of tsetse and sleeping sickness malaria, medical facilities population and communications. An attractive feature is the Historical Section in which maps dating from the time of Homer to the end of the XIX century are reproduced. At the end is a map of the routes taken by some of the European explorers beautifully drawn.

HADDOW A. J. *On the Mosquitoes of Bwamba County, Uganda. I. Description of Bwamba, with special reference to Mosquito Ecology.* *Proc Zool Soc London* 1945 Oct v 115 Pts. I & II 1-13 2 figs. [26 refs]

The isolation of the yellow fever virus from a human case and from *Aedes (Stegomyia) simpsoni* Theo. in Bwamba County Western Uganda in 1941 led to the beginning of an intensive mosquito survey of the area in 1942. This survey is still proceeding and results obtained so far are discussed in Part II of this paper (below).

Part I is concerned with a description of the topography and vegetation of the area the zoogeography of the mosquito fauna and the behaviour of mosquitoes in forest areas.

The Commissioners point out that "The detailed story which has to be told and our critical reviews do not lend themselves readily to summarization. The same limitations apply to anyone who attempts to review this tragic report.

Since the terrible famine in 1769-70 in which 10 million of a population of 30 million are said to have died, Bengal had been almost entirely free from famine till 1943. For more than 40 years India as a whole had escaped from great famines—these had come to be regarded by many as things of the past so that the sight of thousands of victims of starvation in the streets of Calcutta came as a great shock to the public in India. The Commission estimated that the absolute shortage of the rice supply available in Bengal in 1943 was of the order of three-weeks requirements—this was a surprisingly small deficit in view of the widespread starvation that resulted. The Commission believed that the shortage of rice and the disturbed conditions due to the war would not have caused a disastrous famine if the Governments of Bengal and India had taken resolute action at an early stage to ensure equitable distribution of the available supply. Equal blame is attributed to certain sections of the public of Bengal—an atmosphere of greed and panic caused a rise in prices to levels which placed rice beyond the reach of the poorer classes. It was estimated that every death in the famine was balanced by roughly 1,000 rupees of excess profit acquired by the dealers in rice. There was also widespread corruption and a moral and social breakdown on the part of some sections of the community.

Less than two pages out of the 107 in the first part of the report are allotted to a description of the background against which the events which led to widespread starvation in 1943 must be viewed, but these pages are of outstanding importance because they contain a clear statement of the basic causes of the famine as opposed to the causes that precipitated the tragedy—they show that the people of Bengal and of many other parts of India were becoming progressively more vulnerable to the effects of any temporary reduction in the food supply.

It is stated that 7½ million families in Bengal are wholly or mainly dependent on agriculture for their livelihood, that less than 2 million of these hold more than 5 acres each, and that about one-half of them hold less than 2 acres or own no land at all. The general consensus of opinion endorsed by the Land Revenue Commission of Bengal, is that 5 acres would be the minimum area required to keep the average family in reasonable comfort and that for some types of land 8 acres would be needed.

As evidence of the previous nutritional condition of the people the commissioners quote the findings of the reviewer who in 1933 carried out a rough but illuminating survey of certain aspects of life in rural India. This survey was based on the personal observations and opinions of large numbers of dispensary doctors in agricultural villages. These findings are regarded by the Commission as indicating in a general way the unsatisfactory state of nutrition of the people of rural Bengal 10 years previous to the famine. "The doctors in Bengal reported that only 22 per cent. of the population were well nourished and that 31 per cent. were very badly nourished. The following further opinions are expressed on this subject—"Poverty and malnutrition left a section of the population with few reserves material or physical to meet superimposed calamity. For them there was no margin of safety and little possibility of tightening the belt. The fact that such conditions are common to most other provinces of India, which escaped the famine, does not detract from their fundamental importance. Agricultural production was not keeping pace with the growth of population. A considerable section of the population was living on the margin of distress.

In a separate Minute Mr M Afzal Husain one of the commissioners states that since 1933 there has been no increase in food production but a steep rise in population he quotes Dr Aykroyd as having estimated in 1943 that for India as a whole there is at all times serious under nourishment of about one-third of the population and goes on to ask why no attention was paid to the warnings given by numerous investigators on economic agricultural medical and nutritional problems.

The second part of the Report deals with death and disease the official figures show that in the second half of 1943 the number of deaths exceeded the quinquennial average by nearly 700 000 and in the first half of 1944 the excess was over 422 000 These figures are admittedly unreliable In the worst areas 10 per cent. of the people died but all over the province the death rate was much higher than normal. Deaths among infants under one year of age were 26.8 per cent. fewer than normal this surprising reduction was due chiefly to a fall in the live-birth rate which fell from 28 to 18.8 per mille but here again the registration of births and deaths is likely to have been more inaccurate than usual

The mortality curve followed the same general trend as in normal years reaching its highest point in December but of course the level was much higher In May and June 1943 the death rate in the province had already risen to a considerable degree from September to December it rose steeply In the early stages of the famine a high proportion of the deaths resulted from starvation later on epidemic diseases especially malaria and cholera, were the actual causes of most of the deaths

Vitamin-deficiency diseases and pneumonia were far less frequent than had been expected. The medical aspects of death from starvation are being investigated separately so that little is said of them in the Report

The quinine situation was extraordinary in November 1943, about 43 000 pounds of quinine were available in Bengal, but distribution was exceedingly difficult the price on the black market was R.300 a pound so that supplies had to be sent under armed escort to the districts In spite of this precaution the Director of Public Health stated publicly in December 1943 that a vast amount of the quinine issued by Government had gone into the black market Eventually quinine and mepacrine became available throughout the province. In 1943 79 000 pounds of quinine and 20 000 pounds of cinchona febrifuge were allotted to Bengal in 1944 65 000 pounds of quinine 30 000 pounds of cinchona febrifuge half a million ampoules of quinine and 382 million tablets of mepacrine were supplied. Large quantities of sulphaguanidine and vitamin preparations including a million capsules of halibut liver-oil presented by Boots Pure Drug Co. were distributed.

Vaccination against smallpox and inoculation against cholera were carried out on a huge scale especially during the first half of 1944 when more than 23 million persons were vaccinated and more than 11½ million were inoculated.

The last part of the Report deals with food-administration and rehabilitation there is a chapter on protective and supplementary foods it is stated that more meat fish eggs and milk are badly needed The high cost of these articles is mentioned but nothing is said about the practical difficulty arising from the fact that a much larger acreage of land is needed to provide a family with a well balanced diet than to supply enough rice or other cereals to satisfy hunger

The medical relief and public-health services of the province are severely criticized for their failure to take effective action during the early stages of the famine when much could have been done to save the situation The medical personnel had not been severely depleted by war conditions except

for the withdrawal of most of the few members of the Indian Medical Service and Indian Medical Department still remaining in Bengal.

The District Health Officers were poorly qualified and poorly paid servants of the District Boards. The standards of efficiency of the medical officers in general are said to have "left much to be desired—discipline and sense of duty were deficient, and morale low."

In pleasing contrast was the efficiency of the medical and public health officers lent by the army in November 1943—these men by their example and precept at once stimulated the subordinate staff to "unwonted activity."

Special praise is given to the young Indian Medical Officers—the excellence of their work is said to have been a striking testimonial to the value of their military training.

The formation of a provincial cadre of District Health Officers is stated to be an immediate necessity. The control of these officers by local bodies is regarded as being largely responsible for their failure.

(This remarkably frank and outspoken Report deals exhaustively with the circumstances which precipitated the famine in Bengal. Surprisingly little space has been allotted to the basic conditions—referred to as the "background"—which rendered Bengal so susceptible to famine that a relatively small shortage of the normal food supply was enough to cause the tragedy. The significance of these conditions has not been overlooked by the Commission, who describe them as being of fundamental importance and add the common comment that they are common to most of the other provinces of India. It can, therefore, be expected that this aspect of the problem will receive full consideration in the further report dealing with the second part of the terms of reference, which is—*The development of agriculture and the raising of the standards of nutrition so as to make recurrence of famine impossible*." In this term of reference the Commission has been asked to find a solution for the greatest of all the problems that affect the lives and health not only of the people of Bengal and the rest of India but also of more than half the population of the whole world.

The solution would be simple if the inhabitants of the overcrowded countries could be induced to take into account the rigid principle that the greatest quantity of food that can be provided will not be enough for an unlimited number of persons. In these countries reproduction is allowed to occur at the natural rate and this is so high that apart from the checks imposed by premature deaths due to the preventable diseases caused by infection and dietetic malnutrition, the population would double and redouble itself every 25-30 years.

It follows that if complete success is to be achieved in the control of infectious diseases and in securing freedom from want and if at the same time no check is applied to the natural birth rate it will be necessary to provide for a corresponding increase in the food supply. In Bengal for example where an immediate increase in the food supply by 50 per cent. is needed it would be necessary to provide this and a further progressive increase reaching three times the present amount by the end of 25-30 years. Six times the present supply would be needed 50-60 years hence and so on.

It is true that some experts have suggested that when people are well fed and comfortable their reproductive capacity automatically declines and therefore there is no need to expect any undue increase in the population. This view finds no support from actual experience of what happens in India where the birth rate is highest in those parts of the country in which food is most plentiful.

Obviously then, in the absence of control of the number of births the balance of population and food supply in the overpopulated countries must be maintained through the slaughter of the surplus population by infectious

diseases or malnutrition. Normally in such countries both of these factors co-operate in a very effective manner.

The balance can be maintained at a pitifully low economic level as happens in the countries in which the average duration of life is less than half as long as it might be, or it can be maintained at a high level of health and comfort as in the countries in which the control of infectious diseases goes hand in hand with the control of the birth rate whether by celibacy, delayed marriage or the use of contraceptives. The last of these methods has created a new problem, race suicide, but the impoverished countries will have ample time to devise safeguards against this eventuality.

The Bengal famine deserves the closest study by all public health workers in overpopulated countries. It shows that a one-sided policy directed solely towards the control of infectious diseases must fail unless it is accompanied by action to ensure an adequate supply of food.

The task that lies ahead of health organizations in these countries is infinitely more difficult and complicated than the one successfully accomplished in progressive countries whose inhabitants have themselves dealt with the food and population problem and so have provided conditions in which the control of infection has achieved astonishing success.] *John W D Megaw*

COLONIAL OFFICE. Report of the Committee on the Training of Nurses for the Colonies [RUSHCLIFFE Chairman] Cmd 6672. 65 pp. 1 diagram. 1945 Aug. London: H.M. Stationery Office. [1s.]

In November 1943 the Secretary of State for the Colonies set up a Committee under the chairmanship of Lord Rushcliffe to examine the question of training both in this country and overseas for nurses who are to serve in Colonial territories and to make recommendations having regard also to the need in those territories for increased public health activities and for the fostering and developing of community welfare.

The Committee was composed of members with special knowledge and experience of the training of nurses in Britain and also of those with special knowledge of the colonial requirements.

The report which was published in August 1945 is an eminently practical document not only making general recommendations but also giving many detailed suggestions as to how these recommendations might be carried out.

In the main body of the report are given—firstly, accounts of the history and present position of nursing in the Colonies and of the general medical policy there; secondly, recommendations on how training of local nurses might be provided in the Colonies and on how the training of nurses in Britain might be organized so as to enable them to fulfil their task of developing the local nursing services satisfactorily; thirdly, suggestions as to how the recruitment of nurses might be improved and the conditions of service for nurses made more attractive.

In the appendices examples are given of types of legislation and of methods of organization which have been found useful in Britain or in some of the Colonies. Detailed syllabuses for the training of different types of nurses are included. These should prove useful not necessarily for complete adoption but as suggestions for local development. The Committee emphasizes throughout the report the need for research into the most suitable methods of training to suit the local conditions.

The first recommendation in the report is that Representative Nursing Councils and Midwives Councils (or possibly a joint Nursing and Midwives Council) should be set up in each Colonial territory or group of territories. These are for the purpose of controlling and guiding the ordered advancement

[January 1948]

of the standards of nursing by means comparable to those adopted by such statutory bodies as the General Nursing Council for England and Wales and the Central Midwives Board. These Councils would have the duty among others of maintaining Registers of Nurses and Midwives.

The second recommendation is that "Nurses recruited in the Colonies should be trained locally in training schools. An account is then given of the types of training school required, but the Committee add "Colonial nurses who after qualification show special aptitude, should be given every facility for taking post-registration courses in this country or the Dominions."

It is considered that the minimum period of training for admission to the Register of Nurses should be four years, of which the first three should be devoted to "basic training. In the syllabus suggested for this basic training a thorough and well supervised training in medical and surgical nursing is advocated, but emphasis is also laid on the need for study throughout the course of the preventive and social aspects of nursing.

The fourth year of training should be spent in gaining additional experience either in hospital or in midwifery or by taking a community nursing course. The term "Community Nurse" is used in the report to describe the type of nurse who works outside the hospital among the people and whose duties are of a dual nature combining those of a Health Visitor and a District Nurse. It is considered that this type of nurse should be of great value in the Colonies where so many of the people live in rural areas and where so much educational work in health matters is required.

Other points to be noted are — The recommendations that Assistant Nurses should be trained and registered in the more advanced Colonies that in backward areas especially in Colonies where two standards of education exist, two grades of nurses should be trained, the aim being to use the lower grade nurses for work among their own peoples, and to raise the standard of training year by year up to the higher grade. In training these nurses the combined efforts of educational and nursing teachers are required. Throughout the report this need for close co-operation between the educational and medical departments is stressed, and the interesting suggestion is made that as an experiment there might well be set up joint training colleges of residential type comprising student nurses and student teachers and possibly other vocational students.

In the section dealing with the preparation of nurses in the United Kingdom and the Dominions for work in the Colonial Nursing Service should be given a special course of instruction to equip them more adequately for service in Colonial conditions. This course it is thought, should be of about three months duration, and a very detailed syllabus for such a course is given. The Committee state that they would welcome any increase in the preventive outlook during training of nurses in Britain.

The report ends with a useful summary of the main recommendations.

Mary G Blacklock.

SINMONS James Stevens B.S. M.D. Ph.D. Dr. P.H. Sc.D. (Hon.) etc.]
 HEATON Tom F. A.B. M.D. etc.]

 Volume 1 Part 1 India and the Far East. Part 2 The Pacific Area.
 pp. xxvi + 504 32 maps 1944 London William Heinemann, Ltd. [30s.]
 [Review appears also in *Bulletin of Hygiene*]

Experience of war especially of war in tropical countries, has always shown that one of the chief difficulties of a commander is the maintenance of the health of his troops. Examples need not be multiplied, but the notorious

records come to mind—the Walchoren expedition of 1809 the French occupation of Haiti in 1800 the Crimean war the Gallipoli Macedonia and Mesopotamia campaigns of 1914–18 In the war which has recently ended troops have been sent to some of the most unhealthy parts of the world and disease incidence has not been low but in most of the campaigns though there have been some surprises not least of which has been scrub typhus the military authorities have at least known what the risks were. Steps were taken to acquire in advance knowledge of the diseases indigenous to the areas to which troops were moved. In the United States a large number of medical men and women were associated with the Intelligence Revision of the Office of the Surgeon General of the United States Army and these collected a considerable amount of information either from personal experience of the countries concerned or by the laborious process of consulting reports or papers in the world medical literature The reports they made have been brought together and in this volume those dealing with India and the Far East and with the Pacific Area are now published. The editors remark that the authors do not regard this work as final They would have preferred to delay publication until scrutiny under the more leisurely conditions of peace could have been carried out but have consented to publication at this time because so much of the material is of immediate value to many interests and is not readily available elsewhere

The countries described are —*India and the Far East*—Burma Ceylon China Formosa, Indo-China India Japan Korea British Malaya Nampou and Ryukyu Islands Thailand. *The Pacific Area*—Australia Cook Islands and Niue Easter Island Fiji French Oceania, Gilbert Ellice Ocean and Nauru Islands Guam Hawaii Japanese Mandated Islands Johnston Island and Northern Line Islands Netherlands East Indies New Caledonia New Hebrides New Zealand North Borneo Sarawak and Brunei Papua New Guinea and the Bismarck Archipelago Philippines Phoenix Islands Pitcairn Samoa Solomons Tokelau and the Tonga Islands

In each case notes are given of the climate the health services and medical facilities and the common diseases. There is a bibliography for each section and at the end, a series of world maps showing the distribution of certain diseases. The general index is good.

It is evident that information of this kind has as great a value in peace as in war No similar publication on this scale has previously been issued and though no doubt in future an even greater amount of detail will be required the information now made available will be welcomed. It may, perhaps stimulate some countries from which annual medical reports are not now issued, to contribute regularly after the fashion set by others who do so report, to the orderly mass of world medical information. Volumes of this kind soon become out of date and the issue of new editions at reasonably frequent intervals will be a task for the future.

The reviewer has had some experience of the labour of compiling reports of this kind [see the reports on the Far East in this *Bulletin* 1944 August to December] and this entitles him to say that this American team has done its work well.

MEYER MAY, J with the collaboration of HO-DAC DI VO-DINH TUNG
TONG-THAT TUNG & DINH VAN THANG Chirurges tropicales d'urgence.
[*Urgent Surgery in the Tropics.*] Préface de M. le Professeur MONDOR
pp vi+286 9 coloured pls. & 16 figs 1940 Paris Masson & Cie
Editeurs, 120 Boulevard Saint-Germain. [20s]

This work published in 1940 is based on the author's experience whilst Professor of Surgery at the Medical School at Hanoi in Tonking from 1936 to

[February 1946]

ELLIOTT (p. 278) reports three cases of yellow fever in white soldiers in West Africa. All the patients had previously been vaccinated, but two of them died. Nevertheless the low incidence of the disease is good evidence of the value of vaccination.

KIRK and BAYOUMI (p. 374) report the first fatal case of yellow fever to be recorded in a European in the Sudan. Non fatal European cases some extremely mild, have been seen there before, and there have been many fatal cases in the Africans of the country.

Aetiology

STÉFANOPOULO and DUVOLOV (p. 205) show that yellow fever virus, after prolonged maintenance in tissue culture may undergo marked deterioration in both virulence and antigenic power. A strain of virus 17D which had become attenuated in this way was reactivated by passage through the brains of mice. It did not become pathogenic for monkeys but produced immunity in them. After being cultivated in developing eggs, this strain was then used for vaccination of man, with success.

JACOBS (p. 485) has shown that in a mixture containing 10 per cent. human serum and 0.4 per cent. sodium chloride to which is added ammonium sulphate to 1 per cent. strength, at pH 6.3-6.5 yellow fever virus remains viable at 22-25°C., for as much as 20 days. Simple saline solutions are rapidly lethal to the virus, and the addition of serum is at best not very effective in preserving it.

LINARES (p. 277) shows that young cats are relatively unresponsive to yellow fever. He (p. 278) has been able to infect young mice by instilling the virus into the nostrils intact or scarified skin. The same author (p. 278) shows that chicks are susceptible to yellow fever virus injected by various routes and that the virus persists longer in the brain than in the other organs. Virus may be present in the brain, and at the same time immune bodies may exist in the blood.

LINARES (p. 373) has found that filtrates of cultures of *Aspergillus flavus* *Pericillium camemberti* and a species of *Actinomyces* have a lethal effect on the yellow fever virus both *in vitro* and *in vivo*. A mixture of filtrate and virus is not pathogenic to mice and injection of filtrate into these animals protects them against injection of virus several hours later. A non infective mixture of filtrate and virus however possesses antigenic properties and stimulates immunity.

Transmission

CORSON (p. 597) has compiled, from the extensive literature on yellow fever transmission, a list of vertebrates tested for susceptibility to the virus of mites, tetrates in which vacuotropic virus has been shown to persist, and of blood sucking arthropods on which transmission experiments have been made. This list has been made as complete as possible and brings the information up to date.

HECHT and ANDRZE (p. 463) give an account of the mosquitoes of Bolívar State Venezuela, in so far as these may be concerned with the transmission of yellow fever. Special attention was paid to the jungle mosquitoes. [An examination of the table quoted by these authors from an earlier work, and showing the mosquitoes capable of transmission or in which virus has been found reveals certain errors which have crept into the literature see p. 640.] BOSHELL MANKRIGER and OSORIO-MESA (p. 114) have demonstrated the existence of yellow fever virus in *Haemagogus capricornis* and (probably) *Aedes*

Leucocelaenus captured in uninhabited jungle in Colombia. Protective antibodies were found in certain marsupials. *Haemagogus capricornis* is attracted to light travels considerable distances from its breeding places and tends to follow man and mules some distance from the forest.

BEVIER (p 557) contributes a report on the yellow fever service of British Guiana. No case was discovered in the year 1944. The supervision of air craft and railway trains showed that there was a considerable transport of mosquitoes able to convey yellow fever and other diseases.

It is well known that *Aedes aegypti* breeds in fire buckets flower vases in cemeteries drinking troughs and similar small collections of water. CHANDLER (p 32) claims that phenothiazine is the ideal substance for control of such breeding and that it may be applied as a powder or incorporated in glue on small squares of paper which are placed in the water or as a suspension in dilute alcohol. A single application in the proportion of 1 part to 60 000 of water will prevent breeding for three months or more.

HENDERSON (p 374) describes the steps by which a high breeding rate of *Aedes aegypti* in Savannah (on more than one-third of the premises) has been reduced so that it now occurs on no more than 2 per cent of premises.

Immunity Clinical Features

By a series of carefully planned experiments LINHARES (p 279) has shown that in camondongos [Brazilian house rats] passive immunity (lasting 10 days or so) is transmitted from mother to young *via* the placenta and *via* the milk (lasting as long as lactation continues). Antibodies therefore pass through the placenta and also into the milk. There is no evidence that the virus itself does so.

PERLOWAGORA and LENNETTE (p 114) have studied in animals the complement fixation reaction for yellow fever. The antigen for this reaction appears in the serum on the 3rd to 6th day after infection but the antigen is not directly associated with the virus which may exist in the absence of the antigen. The antibody is present in the serum of animals recently recovered from the disease. The test may be useful in diagnosis of human yellow fever. [For previous work by these authors on this test in which antigen was obtained from infected mouse brain see this *Bulletin* 1945 v 42 83.] The same authors (p 802) have found a correlation between the clinical severity of yellow fever and the amount of complement fixing antigen in the blood whereas there is no fixed relation between clinical severity and the amount of liver damage found after death. Moreover the liver changes usually regarded as characteristic of yellow fever can be produced by injection of tannic acid but without the formation of yellow fever virus antigen. The work indicates that the antigen is specific and it was found in all the animals which had been infected with yellow fever. The complement fixation test therefore constitutes a more accurate and reliable method of diagnosis of yellow fever infection than the histopathological examination of tissue such as liver.

DE ASSUMPTÃO (p 277) discusses the differential diagnosis between yellow fever dengue Rift Valley fever sandfly fever and leptospirosis. In spite of certain similarities—clinical and pathological features transmission by *Aedes* production of lasting immunity—there is no cross-immunity between yellow fever and Rift Valley fever.

SELLARDS and McCANN (p 115) produce evidence that the oral administration of choline hydrochloride in monkeys infected with yellow fever has a protective action on the liver. Five of 8 monkeys so treated survived whereas all of 4 controls died. There was evidence of repair in the livers of those treated monkeys which died.

(February 1946)

In the Fourth Interim Report of the Inter Departmental Committee on Yellow Fever Control (p 721) are given recommendations concerning the most important measures of yellow fever control, especially with regard to suppression of *Aedes* breeding near aerodromes, ports and other places on transport routes the disinsectization of aircraft, the vaccination of travellers and those working at aerodromes, and the diagnosis of yellow fever. These should be read in the original. In the *Epidemiological Information Bulletin* issued by the Health Division of UNRRA (p 890) are given the standards for manufacture and control of yellow fever vaccine these are stringent. They cannot further be abstracted, and details should be sought in the original.

HACKETT and BURRIS (p 803) describe their method of testing yellow fever vaccine by intracerebral injection into monkeys. The vaccine contains no serum and is attenuated but in doses containing high virus content is capable of producing severe encephalitis in the monkeys. These monkey tests are a safeguard to man, and issue for human use is controlled by the results of the animal tests. No ieterogenic or other untoward reactions have been recorded from batches released, after these tests for use in man.

SPRAGUE and BARNAUD (p 890) report the cases of two men allergic to egg protein who suffered severe reactions after the injection of yellow fever vaccine and typhus vaccine respectively. They advise that such persons should be excluded from the Services.

Charles Willocks

MALARIA.

OSGOOD S B *Malaria and the Returning Soldier* J Amer Med Ass
1945 June 16 v 123 No 7 512-13

Two persons, a white girl and a white woman, living in the State of Oregon U.S.A., apparently contracted benign tertian malaria from a soldier who had returned from the Pacific area. *Plasmodium vivax* was found in the blood in all three people. The girl and woman lived near a creek where mosquitoes were numerous but, according to the official records no malaria had existed in the soldier who was related to the girl, had lived in a tent about 50 feet away from her house for over two weeks before she got the attack, and had often passed near the woman's house.

Mosquitoes caught near the girl's house were identified as *Anopheles punctipennis* and *Culex tarsalis* and six specimens caught in the woman's house were *Anopheles macdipentris*. The presence of anopheline vectors of malaria in this neighbourhood had not been suspected.

There may have been a third case in a logging partner of the soldier. he was said to have had chills and fever but could not be found for examination.

MELVILLE A R WILSON D Bagster GLASGOW J P & HOCKING K S
Malaria in Abyssinia. East African Med J 1945 Sept, v 22, No. 8
285-84 1 map [10 refs.]

A Mobile Malaria Section of the East African Army Medical Corps carried out malaria surveys in over 50 localities in Abyssinia during the British occupation of that country in 1941-42. Some of the results of these surveys are here recorded.

The Rift Valley traverses Abyssinia from the north of Lake Rudolf north-eastward to the Red Sea. A *gumbea* the chief vector was found throughout

the valley. Other species of *Anopheles* found in the Rift Valley were *A. coustani*, *A. obscurus*, *A. ardensis*, *A. kingi*, *A. d'thali*, *A. demeilloni*, *A. gambiae*, *A. macmahoni*, *A. christyi*, *A. cinereus*, *A. pretoriensis*, *A. maculipalpis*, *A. pharoensis* and *A. squamosus*. Of these species only *A. pharoensis* and *A. d'thali* demand serious consideration as possible vectors. *A. pharoensis* is very common over wide areas, enters human dwellings and bites readily. The few dissections made revealed no sporozoites. This species was always found in association with *A. gambiae* and thus no circumstantial evidence was available as to its potentialities as a vector. *A. d'thali* is strongly suspect. It occurs in the Red Sea littoral. It was the only species found at Mordale (700 metres) where malaria occurs.

A. gambiae was found to be the vector of epidemic malaria in places in which mosquito breeding was dependent on rainy seasons. In other places the species was present throughout the year, breeding in residual pools left in river beds after torrents had subsided. In some of the smaller permanent rivers, pools and gently trickling water provide facilities for *A. gambiae* breeding.

As the level of the country falls from the plateaux of the east and west to the floor of the Rift Valley, malaria endemicity increases till a zone of moderate hyperendemicity is reached between 1,500 and 1,800 metres. At lower levels there may be intense hyperendemic malaria near streams, rivers or lakes, or low endemicity where rainfall is small. In the latter places malaria is essentially seasonal.

Much of Abyssinia north-west of the Rift Valley is free from malaria, most of the country over 2,000 metres being too cold. There may be annual or periodic epidemics of malaria of some severity in this high country, but the endemicity and severity of epidemics are lower than in the Rift Valley. *A. gambiae* is the chief vector here also. At Jimma *A. funestus* was found in fair numbers after the rains and when the swamps had fallen in level. Other *Anopheles* found in the north-west were *A. coustani*, *A. kingi*, *A. nili*, *A. marshallsi*, *A. harperi*, *A. demeilloni*, *A. christyi*, *A. cinereus* and *A. squamosus*.

South-east of the Rift Valley, a massive mountain range forms the watershed of the Juba and Uebi Scebelli Rivers. East of this the land slopes to the low deserts of Somalia. Malaria occurs in varying degree along the slopes of the Chercher mountain range. Transmission is either absent or very brief at Harar (1,930 metres). There are highly endemic areas near Lake Chercher. At Negelli (1,290 metres) malaria transmission is slight and seasonal. Low endemicity characterizes the area including Mega, Moyale, Adola and Ghimir, with the exception of the Dawa, Parma and Ganale Doria river valleys which are highly malarious. *A. gambiae* is the malaria vector in this south-east area. Other species found were *A. coustani*, *A. lesoni*, *A. rhodesiensis*, *A. demeilloni*, *A. cinereus* and *A. pretoriensis*.

THOMSON R. C. M. Studies on the Breeding Places and Control of *Anopheles gambiae* and *A. gambiae* var. *melas* in Coastal Districts of Sierra Leone. *Bull. Entom. Res.* 1945 Sept. v. 36 Pt. 2, 185-252, 8 text figs., 48 figs., on 13 pls. & 8 maps. [27 refs.]

Anopheles melas (for in the text the author accepts RIDDBANDS's view that this is a species rather than a variety [this *Bulletin* 1945 v. 42, 3]) differs from *A. gambiae* not only in the characters described by that author but also in the egg. This has a broad upper surface with the space between the frill and the float so narrow that they appear to be in actual contact instead of the narrow upper surface with a distinct space wide enough to show the polygonal marking of the chorion between the frill and float in *A. gambiae*. The distinction of the

two species on the palpal bands is indefinite. *A. melas* sometimes having three and sometimes four bands and the proportion with each number varying from place to place.

The use of this characteristic has made it possible to identify with certainty the breeding places of the two species. *A. melas* is restricted to coastal areas and brackish swamps, very rarely making use of fresh water. Of 2,647 eggs collected from fresh water unaffected by tides, only 30 were of the *melas* type and these were found in places close to its normal breeding areas.

Breeding of *A. melas* is confined to the stretch of ground between high neap-tide and high spring tide levels, and there only occurs in association with certain flora. *Aricennia nitida* mangrove and sea grass or *Paspalum* Mangrove is of two types the very common *Rhizophora racemosa* with the well-known characteristic of roots like the staves of an inverted umbrella, and *Aricennia nitida*, which resembles an apple tree in appearance. The former is very much the commoner and grows in mud below neap-tide level the latter grows in scattered isolated "orchards," always above neap-tide and below high spring tide level, on ground which is fairly solid and covered with a mat of leaves, but with many pools. On the extreme inland side of mangrove areas of whichever type, there are often areas of sea grass which are inundated by extreme tides and which on account of their position tend to receive also fresh water from seepages as well as from rain. In *Aricennia* orchards, egg laying takes place on the earliest of the spring tides often only on the shore side of the orchard, and the eggs are distributed by the action of the tide, they and young larvae being undamaged by tidal water which may flood the entire area to a depth of a couple of feet. On the subsidence of the spring tides some eggs are left in pools, in which they develop others are stranded in mud, in which they survive until the next series of high tides floats them, when the eggs immediately hatch. In consequence the output of adults is highly periodic, occurring in waves a few days after the end of the spring tides. In *Paspalum* areas egg laying may occur at any time, but is in fact often periodic as a reflection of the varying numbers of adults available to lay. The periodicity and size of the output of adults is dependent on the following factors:—(a) the occurrence of spring tides (b) the periodicity of the tides, as in a single month there may be either one or two series of sufficient height to flood the *Aricennia* orchards (c) the occurrence of rain in sufficient amount to prevent the pools left by spring-tides from drying up before larval development is complete and (d) the presence of seepages maintaining tidal pools, especially in *Paspalum* areas. These factors react together in different ways in different places and at different seasons, but in general, output is greatest in the rainy season, particularly in June when it may be enormous and continues until some months after the end of the rains, when seepages dry up and reaches its lowest levels in the months of January to April. Although egg-laying only happens in coastal brackish water a laboratory experiment suggests that it is not itself dependent on salinity, and the factor which causes this mosquito to choose this type of breeding place is not understood.

Aricennia orchards can be detected from the ground only with great difficulty. They are more readily detectable from above from a nearby hill if such exists or from aircraft. This last is the best method as accurate mapping can be done by aerial photography which has revealed only 17 orchards, many of them minor in the enormous extent of general mangrove in the Free town estuary. Control by drainage is not effective as opportunity for egg-laying and for the persistence of some breeding pools, inevitably occurs after spring tides. Control by embankment to exclude the spring tides from areas of *Aricennia* and *Paspalum* associated with drainage of fresh water through tide gates is much the most successful and completely eliminates breeding.

A summary of dissections by another worker and of which it is said that a detailed report will be published later shows that 42 of 1 000 salivary glands contained sporozoites and 44 of 931 (4.7 per cent) stomachs contained oöcysts the total infection rate being 7.3 per cent.

A. gambiae of the type form breeds in fresh water pools exposed to the sun. Detailed analysis of breeding places and of places not selected for breeding shows that this is only a small part of the story and much remains obscure. Of the apparently suitable pools available only a very small proportion are utilized but these often contain very numerous larvae and continue to do so for long periods and generalizations on breeding habits are impossible or at least dangerous. In the general attack on a type of breeding place it is not uncommon to treat numerous water areas which are in fact harmless and to overlook a few small ones which provide almost the entire local adult mosquito population. Breeding commonly occurs in small pools in sweet potato patches and prolifically in rice fields at all stages of cultivation and throughout the entire season but not throughout the entire extent of the field. In the rainy season profuse breeding occurs along the edge often only a fraction of it in the dry season though the water area is diminished breeding becomes more widespread and the total output of adults may increase. Field trials show that oviposition is not influenced by light and shade or by salinity below 30 per cent of sea water or by surface films caused by iron bacteria (though these films when continuous may prevent larval growth) but is influenced by mechanical obstruction interfering with the flight of the female before oviposition as is the case with *A. culicifacies*.

A. mls has not in the past been regarded as an important vector of malaria in Sierra Leone but it is here shown that in the dry season it may be the most abundant anopheline in some villages and may have very high sporozoite rates. GORDON *et al* [this *Bulletin* 1933 v. 30: 301] found a sporozoite rate of 9.1 per cent and TREDRE is reported as finding one of 3.2 per cent. It must therefore be considered as an important carrier of malaria.

[This paper contains much statistical and geographical information which cannot be adequately indicated in a review and is illustrated by 50 photographs as well as by maps and plans. Any worker concerned in the control of *A. gambiae* in any part of Africa should try to see it in the original.]

DELVILLE J. Infection naturelle d'*Anopheles demeilloni* par oöcystes de plasmodium. [Natural Infection of *A. demeilloni* with Plasmodial Oöcysts.] *Rec Trav. Sci. Méd. Congo Belge* 1945 July No. 4: 112.

The author has found oöcysts (probably of *P. falciparum*) in one specimen of *Anopheles demeilloni* captured in Ruanda.

CAMBOURNAC F. J. C. & SIMÕES J. M. P. Sobre a produção de *Anopheles* nos arrozais de Aguas de Moura. [The Production of *Anopheles* in the Rice-fields of Aguas de Moura.] *An. Inst. Med. Trop. Lisbon* 1944 Dec. v. 1 No. 2: 229-39. 2 graphs.

In a previous publication the senior author described his method for determining the larval *Anopheles* population of rice-fields [this *Bulletin* 1939 v. 38: 920]. The interesting observations then reported have been continued during four successive rice-growing seasons and the results of those observations are here recorded. Malaria is hyperendemic in the Aguas de Moura district. *A. maculipennis atroparvus* is the only vector. *A. claviger* also occurs breeding

in clear cool water but it is scarce and associates neither with human beings nor with domestic animals. It is of no importance as a vector of malaria.

Breeding of *A. m. atroparvus* is at its maximum in May and June. There was considerable mortality among the larvae of all instars which did not appear to be due to an increase of their natural enemies. The proportion of the various instars in the total catch varied with great irregularity. The complete or almost complete absence of pupae after the end of June was a constant and striking phenomenon though larvae in the fourth instar could be found. In the earlier months when pupae were found, their numbers had no constant relation to the numbers of fourth instar larvae. Though the production of adult anophelines ceases at the end of June the number of these insects in catching-stations remains high throughout July and August. This indicates that the length of life of adult *A. maculipennis atroparvus* in natural conditions is from one and a half to two months.

It is estimated that at the height of the breeding season each hectare of rice fields is capable of producing from 30 000 to 35,000 anophelines a day.

ERCHLER, W. Anopheles-Beobachtungen in Griechenland. [Observations on the Anophelines of Greece.] *Deut. Tropenmed. Zeitschr.* 1944 June, v 48, Nos 11/12, 261-72, 9 figs.

PERRET-GENTIL, A. L'observation des réfugiés malarieux dans la section clinique et le laboratoire de l'Institut Tropical Suisse. [Study of Malaria among Refugees carried out in the Clinical Section and the Laboratory of the Swiss Tropical Institute.] *Acta Tropica* Basel. 1945 v 2, No. 2, 97-121 10 figs.

The arrival in Switzerland of a large number of Italian and Yugoslav refugees infected with malaria provided an opportunity for the staff of the Tropical Institute at Basle to undertake an intensive study of a disease that is rare in Switzerland. Very full advantage was taken of this opportunity. This paper records the results of the study of some 185 cases of *P. vivax* malaria.

Apart from the attacks of fever characteristic symptoms were but little in evidence. Pain in the legs was a frequent complaint. Some temperature charts were very atypical. In about a quarter of the cases the fever was quotidian. Often a loss of weight heralded a relapse. In cases in which no merozoites were found in the peripheral blood the injection of certain provocative agents sometimes yielded good results—adrenaline, milk, Caseosan and Pituit glandol were used for this purpose.

In the examination of blood a method is described which gave better results than the thick drop method. Four or five smears are superimposed, each smear being dried by waving the slide in the air before the next smear is spread.

Observations indicated that *P. vivax* has a greater affinity for mature red cells than for reticulocytes. Difficulty was sometimes experienced in differentiating the basophil stippling of red cells from Schöffner's dots in their early stage. Sternal puncture was not more successful in revealing parasites than was the examination of the peripheral blood. Henry's reaction was of little value.

In treatment intravenous injections of quinine-calcium were often used without giving rise to any untoward symptoms—a preparation Calguquine Sandoz in particular proved an active remedy that was well tolerated. Vitaquine Roche in tablet form gave results equal to those given by the usual quinine preparations.

WILSON Margaret E & WILSON D Bagster **Malarial Infectivity in African Soldiers in a Hyper-Endemic Area** *East African Med J* 1945 Sept v 22 No 9 295-7

During a period of six months thick blood films were taken fortnightly from 137 African soldiers who were being exposed to frequent reinfection by alien if not new strains of malaria parasites. The results of the examination of these films are recorded. None of the men was sick when the films were taken. The men belonged to a large variety of tribes and most had a considerable degree of immunity to malaria. They were classified as immune 76 semi immune 42 non immune 19.

The average parasite rate at these examinations was 16.1 per cent. *P. falciparum* 14 and *P. malariae* 2.1 per cent. Crescents were counted against leucocytes or when very few recorded as one or two in the whole thick film. Only three crescent carriers were found with counts of over 10 per 500 leucocytes, two of them being of non immune tribes. Eight had counts of 1-4 per 500 leucocytes. Twenty-eight crescent carriers had counts of less than one per 500 leucocytes. On the assumption that at least one crescent per 500 leucocytes is necessary for successful mosquito infection not more than 1 per cent of these soldiers at any one time was a probable infector. Half of these infectors belonged to the non immune group which formed but one seventh of the men examined.

FREDERICKS M G & HOFFBAUER F W **A Study of Hepatic Function in Therapeutic Malaria.** *J Amer Med Ass* 1945 June 16 v 128 No 7 495-8 4 charts [13 refs]

Thirty-one patients subjected to malaria therapy are the basis of this report. 21 men and 10 women between 28 and 62 years of age. All suffered from acquired neurosyphilis. *P. vivax* was inoculated intravenously in 29 intramuscularly in 2. No manifest liver disease was noted in any of these patients before submission to malaria therapy. All but six of the patients received general diets, the six received liver sparing diets, high carbohydrate, high protein and low fat.

Among the clinical features recorded were loss of weight, symptoms and signs of gastrointestinal disturbance, degree of weakness. Hepatic disturbance was assessed by the quantitative serum bilirubin test, the cephalin cholesterol flocculation test, the amount of urobilinogen in the urine and the sulphobromophthalein dye retention test. The technique of these tests is briefly described. The results obtained are recorded in the form of graphs.

All the patients showed some evidence of hepatic dysfunction, there was jaundice in one patient, enlargement of the liver in four and spider naevi in five, symptoms which correlated with the hepatic disturbance revealed by liver function tests. The weight loss during and immediately after malaria therapy was striking, this can be lessened but not prevented by special diet. More attention should be given to the study and use of protective diets during malaria therapy. Such therapy is admittedly contraindicated in the presence of clinically manifest hepatic disease.

MARSHALL P. B. **Loss of Antimalarial Properties in Quinine Degradation Products.** *Nature* 1945 Oct 27 505-6

A degradation product of quinine was obtained by KELSEY *et al* [this Bulletin 1944 v 41, 923] following incubation of the alkaloid with rabbit

liver *in vitro* It was shown by MEAD and KOEPFLI [this *Bulletin* 1945 v 42 8] to be a simple derivative of quinine in which the H atom at position 2 of the quinoline nucleus was replaced by a hydroxyl group. The present author has investigated the action of the degradation product on *P. gallinaceum* infections of chickens. In one incubation experiment half the rabbit liver emulsion with quinine was treated with alkali, in order to destroy enzymatic activity the other half was untreated. The chloroform extract of the former contained unchanged quinine the latter did not. Both extracts made up in HCl, were used in the treatment. The antimalarial activity of the pure degradation product in dilute HCl was also compared with that of a corresponding dose of quinine. It was found that the above extract in which all the quinine had been metabolized, as well as the degradation product isolated in the pure state failed to reduce the number of parasites in the peripheral blood of the chickens. [SILVERMAN *et al* (this *Bulletin* 1945 v 42 448) found, on the other hand, that it was as effective as the parent substance in inhibiting the respiration of the same parasites *in vitro* but affected aerobic and anaerobic glycolysis to a lesser degree.] The author notes that whereas quinine and quinidine are metabolized in the same way cinchonine and cinchonidine are not metabolized by chick liver suspensions. This fact may be of some significance in preparing new antimalarial products of related type.

3. The specificity of the reaction has been investigated, and lists of substances which do or do not combine with bromothymol blue are included.

THOMPSON, J. H. Large Initial Doses of Atabrine in the Treatment of Benign Tertian Malaria. *J. Trop. Med. & Hyg.* 1944 Dec.-1945 Jan. v 47 No 6 61-4

One hundred American soldiers who had acquired *P. vivax* infections in the Mediterranean area during 1943 were treated for relapsing malaria in England during the following March and April. Seventy-eight of these patients received an initial dose of 0.6 gm. of mepacrine followed by 0.2 gm. after each meal for six doses and then 0.1 gm. thrice daily after meals for 7 days. The remaining 22 patients received 0.2 gm. of the drug every four hours for five doses and then 0.1 gm. thrice daily for 5 days. All the mepacrine was given by mouth in the form of 0.1 gm. tablets. It was always given after meals. If the initial dose was given between meals it was preceded by a pint of chocolate milk, fruit juice or egg nog.

Of the 78 patients who received the large 0.6 gm. initial dose of mepacrine three (4 per cent.) relapsed between 14 and 30 days after completion of treatment. Five (23 per cent.) of the 22 patients on the smaller doses relapsed during the same period of observation. In none of the 100 patients were there toxic symptoms severe enough to necessitate modification of the treatment. Fifteen per cent. had mild abdominal cramp after the initial 0.6 gm. dose 6 per cent. had mild diarrhoea.

The eight patients who relapsed were subsequently treated with still larger doses: an initial dose of 1 gm. followed by 0.2 gm. every 4 hours for 6 doses and then 0.1 gm. thrice daily for a week. This very large initial dose was

given 24 hours after the second or third chill. In four of the cases serial blood smears were taken every 45 minutes after the initial dose. Clumping of the pigment in plasmodia was seen as early as 45 minutes after the initial dose thereafter disintegration became progressively more marked and after about 6 hours destruction was complete. About 6 hours after the 1 gm dose the patients experienced a very violent chill the last and only one. Toxic effects were more in evidence than after the 0.6 gm dose. Four patients had nausea one vomited one had marked diarrhoea and one had mental symptoms. The delirium of the patient with mental symptoms was transitory and may have been due to the fever or mepacrine or both.

ANN TROP MED & PARASIT 1945 Oct 10 v 39 No 2 128-32. Prolonged Oral Administration of Mepacrine. I The Effects on Tests of Organ Function. [The Army Malaria Research Unit Oxford (MAEGRAITH B G *et al*)]

Forty three healthy young male adults were given mepacrine 0.1 gm daily. At the beginning of this study careful biochemical examinations were made on each individual. The examinations were repeated at intervals of approximately three months until the end of the experiment which lasted between 9 to 12 months. The findings in the later tests were compared with those of the initial tests and with those obtained with 13 similar subjects who received no drug. No significant change could be observed in the following—icterus index serum bilirubin fasting blood sugar glucose tolerance fructose tolerance blood urea urea clearance hippuric acid synthesis total plasma protein, albumin globulin ratio in the plasma plasma fibrinogen Takata Ara test blood chloride or qualitative examination of the urine. It is concluded that there is no evidence that this course of mepacrine impairs the efficiency of the liver or kidney. [A brief account of these experiments was published in the *Lancet* 1945 Aug 4 141 (see this *Bulletin* 1945 v 42 863)]

ANN TROP MED & PARASIT 1945 Oct 10 v 39 No 2 133-6. Prolonged Oral Administration of Mepacrine. II Haematological Effect. [The Army Malaria Research Unit Oxford (MAEGRAITH B G *et al*)]

Sixty five women and 30 men (all healthy young adults) were given mepacrine in a dosage of 0.4-0.7 gm. weekly for 4-10 months. During this period there was no significant change in the red-cell count the white-cell count the haematocrit or the erythrocyte sedimentation rate. A small rise in haemoglobin concentration occurred in the men taking mepacrine and also in a control group of 14 men who received no drug. This apparent rise may have been due to some alteration in the standard used for measurement rather than to any true physiological change. It is concluded that this dosage of mepacrine for long periods has no deleterious haematological effect. [See this *Bulletin* 1945 v 42, 863]

GAHAN J B & LINDQUIST A W DDT Residual Sprays applied in Buildings to control *Anopheles quadrimaculatus* *J Econom Entom* 1945 Apr v 38 No 2 223-30

— TRAVIS B V MORTON F A. & LINDQUIST A W DDT as a Residual-Type Treatment to control *Anopheles quadrimaculatus* Practical Tests. *Ibid* 231-5

— & LINDQUIST A W DDT as a Residual-Type Spray to control Disease-Carrying Mosquitoes Laboratory Tests. *Ibid* 236-40

This series of papers constitutes a full enquiry into the efficacy of DDT for the control of adult *Anopheles quadrimaculatus* starting with laboratory

experiments and passing on to small field trials and then to large scale field work.

In the laboratory trials cages of various materials were treated with known quantities of DDT anophelines subsequently liberated into them and the knock-down and mortality studied. The knock-down was noted hourly for the first five hours and the final mortality was recorded at 24 hours. Preliminary trials showed that *Anopheles quadrimaculatus* and *Aedes aegypti* were about equally susceptible and anophelines only were therefore used in later tests.

The concentration of chemical in the spray used does not materially affect the toxicity of the residue if the deposit is the same and 2.5 per cent. DDT was used as the standard. The nature of the vehicle did affect its toxicity to some extent emulsions and suspensions being about equal to each other and a little better than kerosene solutions. The lethal effect was slow and exposures of 2 to 4 hours were required to give kills approaching 100 per cent. in the case of newly applied films and as long as 4 hours in the case of older films. The exposure time required for complete mortality was the same 17 weeks after sprays had been applied and increasing the amount of DDT from 50 to 400 mgm. per sq. ft. of surface did not decrease the time.

Unpainted surfaces treated with the chemical remained lethal for long periods, in some cases as much as a year but the knock-down time slowly increased during this time from about 2 hours to 5 or more hours in films 32 weeks old. On painted surfaces a 100 per cent. kill was recorded 32 weeks after 50 mgm. per square foot had been applied to surfaces coated with cold water casein paint. The duration of effect was however much shorter on surfaces recently treated with oil paint, mortalities below 100 per cent. being recorded when the film was a week old and the knock-down after 5 hours being reduced to 25 per cent.

Exposure of treated surfaces to sunlight reduced the length of time for which they were effective by about half and experiments to determine whether mosquitoes left the treated surfaces before they had received a lethal dose showed that the great majority died within 24 hours of voluntarily leaving surfaces treated in this way.

In the field trials rooms were treated with known doses and the effect on artificially introduced or naturally entering anophelines was studied, the dose was varied from 50 mgm. up to 225 mgm. per square foot and resulted in a reduction of the anopheline population to about 4 per cent. of that in control rooms. The duration of effect could not be studied owing to a natural decrease in the control rooms four weeks after the experiment was started. Mosquitoes attempting to leave the rooms were captured and 95 per cent. of those leaving died within 24 hours.

The authors also studied the biting rate of anophelines not yet knocked down in treated rooms and found that this was about proportional to the numbers surviving in the room and concluded that obvious contact with DDT does not act as a deterrent to biting.

In the large field trial, two areas each of about 9 square miles were selected in rice growing country and all buildings, bridges, culverts and other possible shelters were treated. In the one the average dose was 56 mgm. per sq. ft. and in the other 208 mgm. per sq. ft. and adjacent similar areas served as controls. The object was to see if the general anopheline population in the vicinity of sprayed buildings, as well as in the buildings themselves, could be reduced by the use of residual sprays without employing other methods and this was studied by counting anopheline adults in the treated houses and in nail kegs left as traps throughout the area, and also by estimating the numbers of larvae in local breeding places.

The anopheline counts in houses for four months following the end of treatment are recorded in detail and when compared with adjacent control areas showed a reduction of 91 per cent where 56 mgm per sq ft had been applied and of 99 per cent. where 208 mgm had been used. The counts were normally made in the afternoons when mosquitoes would have been in contact with treated surfaces for several hours the few counts made in the early morning showed a smaller relative reduction but as the great majority of captured adults died in 24 hours it may be assumed that these only reflected the previous night's hatch.

The catches in the artificial traps showed no difference between the treated zones and the controls. There were however a number of confusing factors affecting these results and it is not to be taken as proven that there was no reduction in the general mosquito density.

Estimation of the numbers of larvae in breeding places in treated and controlled zones was done by a dipping technique at weekly intervals after the experiment had started. In each of the 20 counts recorded there was a reduction in the treated area which when compared with the controls amounted to 51 per cent. in the zone where 56 mgm. were used and 63 per cent in the zone where 208 mgm had been applied. In each case the number of small medium and large larvae was recorded and it is noticeable that the reduction of large larvae was less than that of small ones.

DEONIER C C, MAPLE J D, JONES H A, HINCHEY Edna & LIDE P M
DDT as an Anopheline Larvicide—Laboratory Tests. *J Econom Entom*
1945 Apr v 38 No 2 241-3

— BURRELL, R. W, MAPLE J D & COCHRAN J H DDT as an Anopheline
Larvicide Preliminary Field Studies. *Ibid* 244-9

WISECUP C. B & DEONIER C C DDT for the Control of *Psorophora* Mosquitoes
Ibid 250-52.

This series of papers constitutes an enquiry into the effect of DDT as an anopheline larvicide starting with laboratory tests and going on to field studies.

In the laboratory tests early fourth instar larvae of *Anopheles quadrimaculatus* were used and mortality readings were made at 24 and 48 hours after application of the larvicide. In some cases the tests were continued for long periods new larvae being introduced periodically and the effect of rain artificially simulated.

The minimum lethal dose of acetone water suspensions of DDT could not be accurately determined but 98 per cent mortality was seen at a concentration of 0.01 parts per million 55.5 per cent. at 0.005 p.p.m. and some toxicity was shown at 0.00125 p.p.m. It was found to be about 100 times as toxic as phenothiazine and more rapid in action. When applied as a dust and compared with Paris green it was found that doses of 0.005 lb DDT per acre gave 100 per cent kill in 48 hours while 0.1 lb Paris green per acre only gave 85 per cent kill in the same period. DDT had the additional great advantage that it was very resistant to sinking either naturally or after rain its resistance was always obvious but to some extent depended on its physical form micronised DDT surviving 14 to 20 rains while non micronised DDT which would pass a 200-mesh screen was rendered ineffective by three periods of rain. It also depended to some extent on the vehicle as solid solutions in calcium stearate and stearic acid gave the best results a mortality above 80 per cent. being obtained after 86 days with 44 artificial rains. Mixtures with talc were effective for 30 days with 16 rains and those with stearic acid for 33 days with 20 rains.

Laboratory trials were also made of oil solutions applied as a film when 0.05 to 0.1 lb per acre were effective and of emulsions and suspensions with which 0.01 p.p.m. were effective for 8 to 10 days.

Field trials with dusts showed that 0.05 to 0.1 lb. per acre gave 100 per cent. kill but had no residual action. To secure this residual effect 1 to 2 lb. per acre had to be applied usually in the form of a 20 per cent. mixture with the vehicle. The duration of the effect varied with the type of water being longest (up to 8 or 10 weeks) where thick surface vegetation prevented the dusts from being blown to one side and least in the presence of sparse vegetation where application was again necessary two weeks after the first dusting.

Solutions in petroleum oils were less satisfactory than dust mixtures and, mainly owing to the difficulty of getting good coverage of the area with the oil film the effective dose was 0.1 lb. per acre and the resulting kill varied from 75 to 100 per cent. being usually over 90 per cent.

Two types of suspension were used in one DDT was in colloidal solution in the water and in the other it was in solution in xylene which was itself dispersed in colloidal-sized droplets. They showed very high promise and gave 94 to 100 per cent. kill which remained apparent for as long as three months. It is noted, however, that at high concentrations these suspensions were toxic to cold blooded animal life and killed fish, frogs and snakes as well as aquatic insects.

Large field trials were made with the object of controlling *Psorophora* mosquitoes the adult females of which lay their eggs in places liable to flood. Hatching of the egg occurs when the area is flooded and is followed by a very short aquatic stage. Two techniques were tried, in the one the soil liable to flood and containing eggs was treated, in the other surface applications were made to the water after the flood had occurred. In the first technique the application of DDT as a dust was ineffective but the application of solutions and emulsions at the rate of 0.1 lb. per acre at the first flood gave perfect results. Experiments were also made with a self-operating dispenser which released DDT solution automatically when the flood happened and this also was found effective.

Surface applications of 0.1 lb. DDT per acre by dusting, pouring of oil, spraying of oil or xylene emulsions or by using impregnated sawdust gave control, and in this case there was some indication of a residual action at the second time of flooding.

METCALF R. L. HESS A. D. SMITH G. E. JEFFERY G. M. & LUDWIG G. W.
Observations on the Use of DDT for the Control of *Anopheles quadrimaculatus*. *Pub Health Rep* Wash. 1945 July 6 v 60 No. 27 753-74 1 text fig. & 4 figs. on 4 pls.

The median lethal doses of DDT and pyrethrins to laboratory reared *Anopheles quadrimaculatus* as shown by tests in a Peet Grady chamber are —

	LD ₅₀ in milligrammes per 1 000 cu. ft.	
	Males	Females
DDT	7.0	12.0
Pyrethrins	1.0	1.5

When tested as a residual insecticide doses of 40, 200 and 1 000 mgm. per sq. ft. showed no significant differences in initial toxicity the percentage mortality being determined by the period of contact of the mosquito with the treated surface which suggests that some physiological reaction such as the rate of absorption, limits its action. Surfaces treated with heavy doses retain

their toxicity however for a longer period than do those which have received smaller doses a fact which was confirmed in laboratory and field tests. In the former a 60-minute contact of female *A. quadrimaculatus* with films of different strengths and ages produced the mortalities shown below —

Age of Film	Dose of DDT in milligrammes per square foot		
	40	200	1 000
	Per cent	Per cent.	Per cent.
New	100	100	100
1 week	100	100	100
2 weeks	100	100	100
4 weeks	100	100	100
8 weeks	20	71	100
12 weeks	44	62	100
16 weeks	0	22	30

Males were more readily killed than females and shorter periods of contact showed the same general effect of ageing of films. In field experiments the toxicity of films of 20 mgm. per sq. ft. dropped below a useful level after about 18 weeks and this loss of toxicity appeared to be mainly due to crystals flaking off the surface rather than to volatilization. Vibration as in ordinary occupation of a house accelerates this effect.

Practical trials were made of an emulsion consisting of a 1 in 4 dilution of a stock concentrate of 25 per cent DDT 7 per cent Triton (emulsifier) and 68 per cent. xylene applied by means of a portable hand spray with which two men could treat about 20 houses per day. Direct measurement of the efficacy was made difficult by the small numbers of mosquitoes in control houses but liberation of adult mosquitoes into the houses showed that the films remained effective for the remainder of the season the period required for complete knockdown in an inhabited house 8 weeks after treatment being 230 minutes. It was noted that smooth enamelled or smooth papered surfaces lost their toxicity more rapidly than rough wallboard.

Both in houses and experimental kegs left in the open it was noted that those treated with DDT exerted a definite repellent effect and in newly treated houses there was a marked decrease in the biting rate despite the entry of mosquitoes an effect which decreased however with the ageing of the films. It appeared that DDT does not deter mosquitoes from entering a treated room but exerts an irritant effect after they have been in contact with a treated surface for a short time. However at least 95 per cent. and probably almost 100 per cent. receive a lethal dose before leaving houses and the chain of malaria transmission is thereby effectively broken.

Emulsions of DDT solutions in kerosene were effective larvicides when the dose of DDT amounted to 0.1 lb. per acre of water surface. Some difficulty was met in applying powdered DDT from aircraft owing to caking of the substance when its concentration in inert dust exceeded 5 per cent. With dust dilutions of this nature 90 per cent. larval control was obtained over 200 foot swaths at actual application rates as low as 0.05 lb. per acre but this involved carrying a heavy load of inert dust and thereby counterbalanced any advantages gained by applying DDT in this form. The spraying of kerosene solutions from aircraft also presented some technical difficulties and an unduly high payload so that the authors turned to 15 to 40 per cent solutions of DDT in certain polymethylnaphthalenes which when sprayed from a specially developed apparatus on a Stearman plane gave 90 per cent. or better

kills over a swath 200 to 300 feet wide at doses of DDT of less than 0.03 lb. per acre. Considerable trouble was spent on the development of thermal generators DDT solution being discharged into an extension of the exhaust and an apparatus was finally devised which produced a visible aerosol, 90 per cent. of the droplets in which were between 5 and 100 microns in diameter this was satisfactory and gave 90 per cent. larval kills over a swath 300 feet wide at application rates of 0.04 lb. per acre. It was also very effective in killing adult mosquitoes, both caged and wild even when protected by dense woods though for this purpose a dose of 0.4 lb. per acre was needed. Aerosols of this nature were much superior for this last purpose both to smokes with finer droplets and to coarser sprays. Another advantage of this type of application was that it was much less toxic to other aquatic insects than the application of kerosene solutions.

SIMMONS, S. W. & Staff. Tests of the Effectiveness of DDT in *Anopheles* Control. *Pub Health Rep Wash.* 1945 Aug 10 v. 60 No 32, 917-27 3 figs.

The value of DDT as a residual spray has been tested in a series of field and laboratory experiments the scale of which can be estimated from the fact that 33 000 adult *Anopheles quadrimaculatus* have been used in 1,800 individual tests and the main results of which are well illustrated in graphs showing the rate of knock-down of mosquitoes exposed to films of different ages the comparative values of various solutions and emulsions and the comparative pattern of slower knock-down with increased age of film. The least effective vehicle was a Lethane water emulsion which gives an amorphous deposit probably covered by a protective film of the solvent. The most satisfactory emulsion was a 35 per cent. solution of DDT in a light proprietary oil known as PD544 C emulsified in water with 4 per cent. Triton (100) in xylene as PD544 C or 0.5 per cent. "Arctic Syntex A" as emulsifying agents. Emulsions in which the dispersed phase was cyclohexane or cyclohexanone were slightly less effective and about equal to kerosene solutions. [It would appear though not certainly that these tests were carried out on unpainted wood panels. Other recent work suggests that kerosene solutions are much less effective against flies on painted surfaces.] An interesting note is made of the crystal shapes resulting from application in different vehicles which may throw some light on this varying effect. Kerosene solutions leave long fragile needle-shaped crystals. Crystals from emulsions are on the whole smaller in some cases less fragile and more compact while Thanite and Lethane leave amorphous deposits which may be covered by a protecting film of the solvent.

The effect of varying the dosage of DDT is to vary the minimum period of contact needed to secure 100 per cent. mortality but as a practical point it seems that films ten weeks old, varying from 50 to 300 mgm. per sq. ft. give about the same mortality amongst mosquitoes exposed to them for 90 minutes though after the ten-week observation period the 50 mgm. dose may lose toxicity earlier than the 100 mgm. dose.

The overall cost of treating the average tenant house (1 700 sq. ft. of wall and ceiling surface) with a DDT xylene Triton-water emulsion at a dose of 200 mgm. per sq. ft. varied from \$1.50 to \$1.75 and this low cost is considered to prestage a degree of malaria control not previously obtainable. A series of releases of 800 to 2,000 mosquitoes in treated rooms showed that this dose was still effecting a complete kill after 22 weeks.

When applied at a dose of 0.1 lb per acre either in surface films emulsions or suspensions DDT will kill all anopheline larvae within 24 hours. The technique used was to prepare emulsions or other vehicles of such a strength that a total quantity of 15 to 20 gallons per acre gave the required dose of 0.1 lb and considerable saving was thus achieved in material costs compared with oil [but not in labour costs]. In making surface films an emulsion of DDT/oil solution was made in water using an emulsifying-spreading agent [1.25 per cent DDT 0.5 per cent B-1956 (an emulsifying-spreading agent) in No. 2 fuel oil of which one gallon is mixed with 15 to 20 gallons water]. A type formula for emulsions was DDT 35 per cent in xylene with Triton X 100.

Duponol OS or comparable emulsifiers and suspensions were prepared by dissolving the DDT in a water miscible solvent such as alcohol and adding to water with a dispersing agent.

From 90 to 95 per cent of the kill takes place within the first hour after treatment and the residual effect wears off within a few days though the sub-surface water when abstracted and tested in the laboratory remains toxic to larvae for a rather longer period. DDT has virtually no effect on plankton and some larger forms of life such as *Daphnia*. When the dose is considered not in relation to the water surface but in relation to its volume quantities between 0.02 and 0.2 parts per million have very similar effects.

The ultimate destruction of the DDT seems to be the result of action by the bottom mud complex as laboratory trials show that destruction takes place much more rapidly in its presence than in its absence.

TRYPANOSOMIASIS

HARDING R. D. Late Results of Treatment of Sleeping Sickness in Sierra Leone by Antypol, Tryparsamide, Pentamidine, and Propamidine, Singly and in various combinations. *Trans Roy Soc Trop Med & Hyg* 1945 Oct v 39 No 2 99-124

This is an account of the effects of treatment followed for 13 to 28 months (in a few instances up to 46 months) in 2713 cases of sleeping sickness in the Kailahun District of Sierra Leone. A report on the earlier results of treatment in a large proportion of these cases has already been published [this *Bulletin* 1943 v 40 370]. Deaths since the start of treatment totalled 228 (of which 181 were attributed to sleeping sickness or the toxic effects of the drugs employed) and only 126 cases remained untraced.

The courses of treatment employed were as follows —

- (i) Antypol five doses of 1 gm. at 5-day intervals in cases with a normal cerebrospinal fluid cell count.
- (ii) Tryparsamide six to ten doses of 2 gm. at 5-day intervals. The majority of patients received nine or ten doses.
- (iii) Antypol, three doses of 1 gm. followed by tryparsamide three to five doses of 2 gm. all at 5-day intervals.
- (iv) Three other combinations of antypol and tryparsamide designed to reduce the toxicity exhibited by Course iii —
 - (a) Antypol, three doses of 1 gm. followed by tryparsamide three to seven doses of 2 gm. An interval of 5 or 7 weeks separated the first and second doses the remainder being given at 5-day intervals.
 - (b) Antypol, two doses of 1 gm. followed by tryparsamide four to six doses of 2 gm. at 5-day intervals.
 - (c) Antypol one dose of 1 gm. followed by tryparsamide eight or nine doses of 2 gm. at 5-day intervals.
- (v) Pentamidine eight to twelve doses of 50 to 100 mgm. daily.
- (vi) Propamidine, eight doses of 50 to 75 mgm. daily.

The remaining three courses constituted a small-scale trial of a combination of pentamidine and trypanamide administered concurrently —

- (vi) Pentamidine five doses of 100 mgm. and trypanamide, five doses of 2 gm., at 5-day intervals. On each treatment-day both drugs were given, the pentamidine first, and trypanamide about two hours later.
- (vii) Pentamidine, five doses of 100 mgm. daily and trypanamide five doses of 2 gm. at 5-day intervals. Trypanamide was given on the first treatment day pentamidine on the 2nd to 6th days inclusive and trypanamide again on the 7th, 12th, 17th and 22nd days.
- (ix) Trypanamide alone five doses of 2 gm., at 5-day intervals, to serve as a control for Courses vi and vii.

Cerebrospinal fluid cell-counts had been made before treatment in 1170 cases in 579 of whom this examination was repeated usually together with an estimation of total protein, at the final follow-up. Cerebrospinal fluid was also examined, at the final follow-up in 383 other patients in whom lumbar puncture had not been performed at the start of treatment.

The author discusses the relative importance of various criteria in assessing the results of treatment —

- (i) *Clinical condition* — This is regarded as unreliable since some patients with considerably raised C.S.F. cell-counts may appear quite well, whilst others with normal counts may present symptoms which superficially suggest relapse but which are really attributable to other causes.
- (ii) *Presence or absence of trypanosomes* — This is valueless, since trypanosomes were only found in four instances (two in gland juice one in blood, and one in C.S.F.) in 132 cases re-examined subsequent to treatment, and the true incidence of treatment failures is certainly higher than suggested by these figures.
- (iii) *C.S.F. picture* — This is considered the only reliable criterion of cure in survivors, though it may perhaps be complicated by the co-existence of yaws in a community since this disease apparently may rarely give rise to slight abnormality of the cerebrospinal fluid (this *Bulletin* 1936, v 33, 963 1940 v 37 25 1942, 39 46). However yaws probably invalidates the criterion only to a very slight extent in 20 random individuals who had no history of sleeping sickness, and an unknown history in regard to yaws (which affects considerably more than half the population of this district at some time of their lives, generally in early childhood). Harding found that 19 showed 5 cells or less and one showed 6.7 cells per cmm. of C.S.F.

A cell-count was considered to be a more sensitive index of the results of treatment than a total protein estimation. Thus, in 917 fluids examined for cells and protein, at the final survey 71 were abnormal in that they showed cells above 10 or protein above 35 mgm., or both these features, but only 7 of the cases showed protein above 35 mgm. combined with a cell-count of 10 or less. The omission of protein estimation would, therefore, have entailed an error of about 10 per cent in recording abnormal fluids, but in calculating total numbers of cases in which treatment failed, including those patients who died or became blind, the error would be no more than about 2 per cent.

In a minority of cases the cell-count was found to remain slightly raised up to three or four years after treatment even though there seemed every indication that the patient was cured. For this reason the author adopts 10 cells per cmm. as the limit of normality in assessing the cure-rate, but in order to satisfy the most stringent standards he has also worked out cure rates on the basis that five cells per cmm. represents the upper limit of normality after cure. A definite decision as to cure cannot be reached within about 14 months after treatment.

- (iv) *Mortality* — A history of death from sleeping sickness is, of course, of prime significance in assessing the results of treatment so long as the accounts of relatives and friends can be relied upon, as was found generally to be the case among the people concerned.

The author treats his findings by statistical methods designed to show the comparative value of the various forms of drug therapy in the mass treatment of a sleeping sickness outbreak which exhibits the distribution of evolutionary stages of the disease (as revealed by C.S.T. cell-counts) encountered in this particular epidemic. The distribution as percentages of all cases of sleeping sickness in which lumbar puncture was done before treatment was as follows: 0-5 cells per cmm. 52.2 per cent 6-20 cells 26.1 per cent 21-100 cells 9.1 per cent. more than 100 cells 12.5 per cent. The statistical methods used are fully described and are similar in principle to those generally employed in calculating standardized death rates from crude death rates.

Course iii comprising three doses of antrypol followed by three to five doses of tryparsamide all at 5-day intervals proved to be highly toxic being followed by a standardized death rate of 6.4 per cent within three months of treatment. However the toxicity and death rates associated with this course were considerably reduced by the adoption of course iv where there was an interval of five to seven weeks after the first dose of antrypol or where only one or two doses of antrypol preceded the administration of tryparsamide. In fact this course (iv) proved to be the most successful of all with a standardized cure rate of 93.5 per cent. Attempts to determine the underlying reasons for the exceptional toxicity of Course iii were unsuccessful and the author considers that the most likely explanation of the great reduction in toxicity when the course was modified by merely allowing an interval of five to seven weeks between the first two antrypol doses is that the long interval allowed time for recovery in the patients' general condition after the initial dose had destroyed all trypanosomes in the peripheral circulation.

Course ii (tryparsamide alone) was rated inferior to course iv largely because of the high incidence of blindness—5.6 per cent though the figure is somewhat weighted by the high proportion of late cases treated and vision is more frequently impaired in these than in early cases. Courses v and vi (diamidines) were inferior because of their failure to cure late cases.

A satisfactory rule for all occasions was eventually worked out if it is convenient to arrange an interval of 3 weeks or more without treatment after the first dose of antrypol has been injected then a further two of antrypol followed by five of tryparsamide are given. If the interval is between 2 and 3 weeks only one further antrypol and six tryparsamide are given and if the interval is less than 2 weeks then no further antrypol is administered and the course is completed with seven doses of tryparsamide. This rule has since been applied over many thousands of cases and it has been consistently found that no more than about 1 per cent of patients die during treatment and no more than 1 per cent become blind.

An important part of the paper deals with the value of combined treatment by antrypol or pentamidine and tryparsamide. The author writes that it is generally less upsetting to the African peasant's farm work and normal life to visit a treatment centre once every 5 or 7 days than to visit it daily for the same number of times whereas such a patient would not be willing to make a journey of more than 3 or 4 miles daily for perhaps 10 days he will and does walk four times that distance regularly once in 5 days on ten occasions. Greater practical advantage would therefore accrue from reducing the number of attendances necessary in the spaced type of course while retaining its effectiveness than from reducing the intervals between injections. Such an aim might be realized by employing a combination of tryparsamide with another drug such that the two compounds could be administered concurrently in full doses without undue toxicity. Antrypol as the second drug does not meet the need because when given concurrently with tryparsamide the dose of one or both drugs must be substantially reduced for the combination to be

tolerated. Pentamidine however was safely given in full doses of 100 mgm. combined with five full doses (2 gm.) of trypanamide both drugs being given on each of five injection days at 5-day intervals, so that the whole course was completed in the short span of 3 weeks. The small-scale trials of combined pentamidine and trypanamide (Courses vii to ix) involving 84 cases appeared to give very promising results but it was not possible to claim any superiority of the combination over trypanamide alone since the average Sierra Leone patient is so readily cured by trypanamide without any adjuvant. The risk of toxic sequelae and visual impairment with the pentamidine trypanamide combination appears to be very slight and the author recommends it for more extended trial in other parts of West Africa, where the average case is less responsive to treatment with trypanamide.

The author has also studied the protection against subsequent reinfection conferred by treatment. In 1 732 cases comprising 1 610 probable cures and 122 relapses re-examined at the final follow-up trypanosomes were found in only four cases, although at least 41 reinfections might have been expected among the cured cases on the basis of the prevailing infection rate of the general population in the interim between mass-treatment and follow-up. Of these four cases three had been treated by trypanamide alone and probably were in fact reinfected individuals because they had large soft glands suggestive of recent infection, and an almost normal C.S.F. picture. The fourth patient who had received antrypol was probably suffering a relapse, being clinically far advanced and with a high C.S.F. cell-count. In summary then no reinfections were demonstrated in 1,307 cases treated by courses containing antrypol or a diamidine though 33 might have been expected, whilst three reinfections occurred among 300 cases treated by trypanamide alone when eight might have been expected. The tentative interpretation offered is that all the treatment-courses produced a temporary immunity due to the destruction of trypanosomes while antrypol and the diamidines (but not trypanamide) exerted in addition a prophylactic action persisting for over a year. Harding writes that these findings are not necessarily representative of results which would be obtained in all parts of West Africa and much depends no doubt on the local strain of trypanosome. In one small area in Nigeria, for example he found trypanosomes in a large proportion of cases of relapse after treatment by trypanamide alone but in general his experience has been that trypanosomes are rarely to be found in relapses after combinations containing antrypol. Nevertheless in another part of Sierra Leone where an unusual type of the disease prevails about 9 per cent. of a group of cases revealed trypanosomes 18 months after treatment with a combination of antrypol and trypanamide but whether they represented relapses or reinfections was not determined. Taking all such variations into account, the author's view is that it probably remains true that in most types of West African trypanosomiasis, the inclusion of antrypol, or of a diamidine in treatment courses reduces the danger to the community arising from the possibility of subsequent infections relapse or reinfection among the cases treated.

DIAS E. & DE FREITAS L. Jr. Introdução ao estudo biométrico dos hemoflagelados do género *Schizotrypanum*. I. Introdução material e técnica. problema e métodos estatísticos. [Introduction to a Biometrical Study of Haemoflagellates of the Genus *Schizotrypanum*. I. Introduction, Material and Technique, the Problem and Statistical Methods.] *Mém Inst Oswaldo Cruz*. 1943, June 1 38 No. 3 427-36 1 fig. [14 refs.]

This is the first instalment of a series of papers devoted to a biometrical study of *Trypanosoma cruzi*-like haemoflagellates which the authors refer to

the genus *Schizotrypanum*. This group comprises trypanosomes parasitic in various species of mammals and especially bats in different parts of the world. Since these trypanosomes are morphologically similar to the parasite of Chagas's disease it is important both from the aetiological and epidemiological points of view to determine whether they represent one species or a number of distinct species.

In the present paper the authors describe the methods employed for the differentiation of various strains of trypanosomes measured in blood films stained by one of the Romanowsky methods. In each strain 50 trypanosomes are drawn with the aid of a camera lucida at a magnification of 1500. The measurements are then made with an opisometer along a line running through the middle of the body of the trypanosome from the posterior end to the tip of the flagellum. They comprise the following elements: (1) Distance from posterior end to middle of the nucleus (PN) (2) distance from middle of the nucleus to anterior end of the body (NA) (3) length of free flagellum (F1) (4) total length (T) (5) nuclear index (IN) representing PN/NA.

The statistical problem was to determine whether the strains thus measured belonged to the same or to different populations. The authors consider that from this point of view the most important elements are NA and the mean nuclear index (INM) which is the mean of the individual nuclear indices (IN) of a strain. The strains are compared with each other by calculating the arithmetic mean of each series of measurements and the standard errors of the differences between the means and also by applying Pearson's χ^2 test.

DIAS E & TORREALBA J. F. Verificação de flagelados semelhantes ao *Trypanosoma rangeli* Tejera em *Rhodnius prolixus* alimentados em caso de doença de Chagas na Venezuela. Considerações sobre a natureza deste protozoário [Flagellates similar to *Trypanosoma rangeli* in *Rhodnius prolixus* fed on a Case of Chagas's Disease in Venezuela. Discussion of the Nature of this Protozoon.] *Mem Inst Oswaldo Cruz* 1943 Dec. v 39 No 3 265-78 35 figs on 2 pls [12 refs] English summary.

In 1920 TEJERA [see this Bulletin 1921 v 17 97] described under the name *Trypanosoma* (or *Crithidia*) *rangeli* a flagellate represented chiefly by crithidial forms which he found in the gut of *Rhodnius prolixus* from Venezuela. In some of the bugs this parasite occurred alone in others it was accompanied by metacyclic forms of *T. cruzi*. Tejera suggested that this parasite might also have some vertebrate host.

In the present paper the authors claim to have isolated *T. rangeli* from man. The case in question was in a child in Venezuela who showed symptoms of acute Chagas's disease. The patient's blood was inoculated into a guinea-pig and laboratory-bred *Rhodnius prolixus* were fed on the patient for xenodiagnostic purposes. The bugs thus fed became infected with flagellates which comprised crithidial forms similar to *T. rangeli* and metacyclic trypanosomes while in the blood of the guinea-pig were found trypanosomes of the genus *Schizotrypanum* to which the authors refer *T. cruzi* and some closely related bat trypanosomes. The trypanosome in question was differentiated from *T. cruzi* biometrically its closest affinities being with *T. phyllostomae* a bat trypanosome previously suspected of being capable of infecting man. The same trypanosome was also seen in a monkey inoculated from infected bugs and in guinea-pigs through which the strain had been passaged. However the flagellates which developed in Triatomid bugs fed on these animals did not belong to the *rangeli* type but were of the *cruzi* type.

In discussing the nature of the new trypanosome the authors dismiss both the possibility of a mixed infection (*T cruzi* and *T rangeli*) in the bugs since these insects had been bred in the laboratory and the possibility of it being an atypical strain of *T cruzi*. They attribute all the stages seen in the bugs and in the mammals to *T rangeli* which they regard as a pathogenic human trypanosome.

[There are a number of conflicting facts in this paper which stand in need of further elucidation before the authors' conclusions can be accepted. (1) It is admitted that the symptoms in the patient from whom "*T rangeli*" was isolated were those of typical Chagas's disease as produced by *T cruzi*. (2) The blood-form of *T rangeli* has the general appearance of *T cruzi* from which it differs only in its mean nuclear index (see DIAS & FREITAS, above) and mean total length. In other words there is evidently considerable overlapping in the dimensions of the two trypanosomes which would hardly justify their separation into distinct species especially as no information is given regarding the degree of variation in undoubted strains of *T cruzi*. (3) It would appear that while the crithidia in the bugs infected from the patient correspond to Tejera's *T rangeli* in having a small kinetoplast both the blood form of the new trypanosome and its metacyclic form in the bug have a large kinetoplast like that in *T cruzi*. Since the kinetoplast of a given trypanosome retains its characteristic size throughout the entire cycle of development in vertebrate and invertebrate hosts the discrepancy found in the present case (but not commented upon by the authors themselves) is rather suggestive of a mixed infection of *T cruzi* and Tejera's flagellate. (4) The problem is further complicated by the fact that *rangeli*-like crithidia developed only in the bugs which had fed on the patient, but not in those which were subsequently fed on experimentally infected animals.]

ROMAÑA, C. & TERRACINI, E. Infección de lauchas por *S. cruzi* a través de la piel intacta. [Infection of Mice via the Intact Skin.] *An Inst de Med Regional Tucumán*. 1945 Aug v 1 No 2, 135-40. [10 refs.] English summary

"(a) The authors have obtained with *S. cruzi* the infection of mice through the apparently intact skin.

(b) The prepatent period lasted 73 days in the infected animals.

(c) The infection showed a chronic character from the beginning

ROMAÑA, C. & TERRACINI, E. Comportamiento de las infecciones de lauchas por *S. cruzi* según la concentración de parásitos inoculados. (Infecciones crónicas iniciales). [The Course of Infections of Mice with *T. cruzi* according to the Number of Parasites Injected.] *An Inst de Med Regional Tucumán*. 1945 Aug v 1 No 2, 141-64. 5 graphs. English summary

LARCHER, M. & ROMAÑA, C. La puerta de entrada cutánea en los casos humanos de enfermedad de Chagas. [The Portal of Entry in Human Cases of Chagas's Disease.] *An Inst de Med Regional Tucumán*. 1945 Aug v 1 No 2, 165-73. 3 figs. [12 refs.] English summary

The local swelling associated with the bite of the vector of *T. cruzi* has often been described but the authors here give a detailed account of the lesion. It is red, oedematous, hard and slightly painful on palpation. The associated glands, preauricular and submaxillary are tender and if sections of the former are examined, developmental forms of *T. cruzi* are seen, and soon general symptoms appear and trypanosomes are present in the blood. In some cases

the site of the bite is like a furuncle or an anthrax pustule of mild intensity in others there is superficial rather than deep extension and an erysipelatoid condition is produced. It then gradually clears up the skin becomes dry and undergoes a furfuraceous desquamation leaving a small nodule or a pigmented spot

A case in point is detailed. A man of 27 years the primary lesion was at first thought to be pyogenic and he was treated with sulphonamides but without benefit. He also had a rose rash on the chest and shoulder slightly raised disappearing on pressure. The primary lesion of the eyelids and face were erysipelatoid next day and then began to clear up. A fortnight after admission the patient complained of pain in the bones especially the long bones. Complement fixation was now weakly positive. In another fortnight the reaction was definitely positive and after another 14 days strongly so. The local lesion gradually disappeared and two months after admission to hospital the only indication of it was a slight pigmentation of the skin.

ROMANA C. Parasitismo por *S. cruzi* de válvulas de corazón de perro [Infection of the Cardiac Valves of the Dog with *T. cruzi*] *An Inst de Med Regional Tucumán*, 1945 Aug v 1 No 2 207-11 2 figs English summary

The author refers to the finding in the atrio-ventricular valves of a dog's heart of focus of multiplication of *S. cruzi* describing the local histopathological reaction produced by the parasite

ENGEL R. Tumorstwachstum und Chagaskrankheit [New Growths and Chagas's Disease] *Klin Woch* 1944 Mar/Apr v 23 Nos. 9/16 127-9 3 charts [11 refs]

ROSKIN and ROMANOWA have reported the cure of experimental cancer by means of the toxin of *T. cruzi* but says the author the story of the treatment of cancer is loaded with uncritical communications and defective experiment. Next Rudolf SCHMIDT as long ago as 1910 decided that he was convinced by statistical figures that those who had recovered from several infective diseases were less liable to malignant disease than those with a low infective index.

ROSKIN and ROMANOWA (*Acta Cancerol* 1935 v 1 323) noted that in Chagas's disease after the acute stage subsides the trypanosomes disappear from the blood and collect in leishmania form in the heart brain and internal organs and when present in tumour cells. Next if tumour emulsion and *T. cruzi* are inoculated together the latter infection gains the ascendancy the tumour dwindles and may even disappear altogether. They went a step further and prepared a toxin of the trypanosome from centrifuged citrated blood cooling it and again heating to destroy the trypanosomes themselves, and they claimed that increasing doses of this endotoxin-containing material first retarded and then prevented the growth of the tumour without harming other tissues or organs.

The author has carried out experiments with large numbers of mice which are very susceptible to *T. cruzi* infection the tumour being one to which mice are liable (mouse ascites tumour). These experiments were carefully performed, but the author was unable to confirm the work or report of Roskin and Romanowa. The toxin in the acute stage had no beneficial effect on the tumour growth and the tumour was absolutely unaffected in its course by Chagas's disease in its chronic stage or after cure. So much for the mouse tumour the application to cancer in human beings has not yet been tested [but one gathers from the general tone of the paper that success would come as a surprise]

TALICE, R. V. & LÓPEZ FERNÁNDEZ, J. Primeros ensayos de tratamiento de las formas agudas de enfermedad de Chagas con un nuevo arsenical (ácido *p*-arsenofenilbútrico) [Trial of a New Arsenical in the Treatment of Acute Chagas's Disease.] *Arch. Uruguayos de Med. Ciruj. y Especialidades*. 1945 July v 27 No 1 33-46, 3 charts. English summary

The best treatment hitherto known for acute cases of Chagas's disease has been Ac. 7602, a German preparation which of late has not been obtainable. The preparation here referred to is *p*-arsenophenyl butyric acid, with the formula

It has been found of service a year ago for African trypanosomiasis by EAGLE the protozoon disappearing from the blood within an hour of the first injection.

For cases of American trypanosomiasis it has been used in a 2 per cent. solution in distilled water injected intravenously or intramuscularly three times a week in doses of 0.015 cc. per kilo body weight till 12 doses have been given. Three cases are recorded in this paper—two children, of 5 and 12 years respectively and an adult of 26 years. All three were clinically typical cases. The children tolerated the drug well the adult had albuminuria after the second injection which necessitated reduction of the dose and longer spacing between injections (but no details are given of this reduction or lengthening of interval). The results noted are not too optimistic—the fever dropped in four days but other symptoms persisted, though the regional adenopathy was reduced. Xenodiagnosis positive before treatment was started, became negative after four days, but in the two children was again positive when they left hospital after the 12th injection. In untreated cases even when the form of disease is mild, the trypanosomes persist for a month at least. The clinical evolution of the disease seems to be uninfluenced. The fact that in the children the xenodiagnosis was negative for short periods only—7 and 12 days respectively while it remained so in the adult, leads to the observation that larger doses should be given to children suffering from this disease.

TALICE, R. V. Ensayo de tratamiento de la forma aguda de la enfermedad de Chagas por la penicilina. [Treatment of Acute Chagas's Disease with Penicillin.] *Arch. Uruguayos de Med. Ciruj. y Especialidades*. 1945 Aug., v 27 No. 2, 152-7 [chart & 4 figs. English summary]

One acute case of Chagas disease, in a 11 years boy has been treated with penicillin intravenously. The total doses reached to one million Oxford units which were distributed through 12 days of treatment.

The treatment had no beneficial action either from a clinical or a parasitological standpoint. The patient left the hospital still with a mild, slight fever and 12 xenodiagnoses carried on every day were all positive.

"Although only one case has been treated, we think that penicillin has no action over *Trypanosoma cruzi* infections. This result confirms our own experiments on laboratory animals."

PÉREZ, A. & ROMANA, C. Estado actual de antiguos casos de enfermedad de Chagas en una familia de Monteros (Tucumán) [The Present Condition of Patients with Long-standing Chagas's Disease in a Family] *An. Inst. de Med. Regional Tucumán* 1945 Aug v 1 No. 2, 213-28 6 figs. English summary

Within the same family the authors establish the existence of —

"(a) An old acute case of Chagas disease the first described in Argentina, 20 years ago now seemingly a simple carrier of *S. cruzi*

(b) An old case of Chagas disease with an apparent *spontaneous cure* examined 15 years afterwards. The isolated strains in both cases during the acute period showed little virulence.

(c) Finally the father had a myocardiac lesion probably caused by Chagas disease.

LEISHMANIASIS

GAST GALVIS A & RENGIFO S. Leishmaniosis visceral. Estudio epidemiológico del primer caso diagnosticado en Colombia. [First Case of Kala Azar diagnosed in Colombia.] Reprinted from *An Soc Biol Bogotá* 1944 Sept v 1 No 4 8 pp 3 figs.

During the course of a viscerotomy survey being carried out in Colombia in order to identify deaths from yellow fever sections of the liver from a child three years of age were found to contain numerous leishmania. The case was evidently one of kala azar the first to be identified in this country. A careful study of the inhabitants of the district San Vicente de Chucurí Department of Santander failed to reveal any other case. There was a 9.33 per cent incidence of malaria, a fact which renders difficult the recognition of cases of kala azar. During the survey which was carried out a number of cases of cutaneous leishmaniasis were seen. A study of the arthropods of the district showed that 15 species of *Phlebotomus* were represented. C M Wenyon

DA CUNHA A M. A soro-aglutinação das leishmanias [Serum Agglutination of the Leishmanias.] *Mem Inst Oswaldo Cruz* 1942 v 37 No 1 35-76 English summary

The author has investigated the possibility of identifying species of *Leishmania* by agglutination tests carried out with sera prepared by immunizing rabbits with culture forms of the organisms. The species employed were *L. tropica*, *L. infantum* and *L. donovani* of the Eastern Hemisphere and *L. brasiliensis* and *L. chagasi* (*L. donovani*) of the Western Hemisphere. A number of different strains of each species some of which had been in cultivation for years and others recently isolated, were used. Agglutination tests and absorption tests were carried out. The general results are given in a series of tables. It is concluded that all strains when freshly isolated have the same antigenic constitution. It was noted that when a serum which had been prepared against a freshly isolated strain is absorbed with an old strain the amount of agglutinin left free is much smaller than when a serum prepared against an old strain is absorbed with a newly isolated strain. It was shown that by absorbing equal amounts of serum prepared against a new strain by equal amounts by weight of a new and an old strain a newly isolated strain absorbs a larger amount of agglutinin than does an old strain. The absorbed sera were made to act on recently isolated as well as on old strains with the object of deciding whether the newly isolated strains contained a greater amount of the common antigen or whether they possessed a Vi antigen. The result indicated that the former view was correct. The antigen in newly isolated cultures is a common or primitive antigen which with increasing age of the culture is subject to modifications due to the production of secondary antigens which are not species-specific. The final conclusion is that species of *Leishmania* cannot be identified by serological agglutination tests. [Though this final conclusion may be correct as also the assumption that freshly isolated strains of all species contain a common antigen it is not clear that the recently

isolated strains contain no other antigen for the author has not applied the methods now generally employed for the antigenic analysis of bacteria and viruses e.g. exposure to the action of heat and various chemicals. The application of such tests might show that the results are capable of a different interpretation.] C. M. Wenyon.

SWENEY, J. S., FRIEDLANDER, R. D. & QUENZ, F. B. Kala-Azar (Visceral Leishmaniasis) simulating Splenic Anaemia. *J Amer Med Ass* 1945 Aug 4 v 128 No. 14 1020-22, 3 figs.

The case described is that of an Italian enlisted man 22 years of age who was admitted to hospital in Utah U.S.A. for an acute surgical condition of the abdomen. There had been a two-years history of illness which had commenced in Sicily. Numerous examinations failed to reveal the cause of the splenic enlargement and marked leucopenia which were features of the case. Finally the case was considered to be one of splenic anaemia. The spleen was removed, and a correct diagnosis was established by the discovery of leishmania in sections of the organ. Many previous examinations of preparations of the blood and bone marrow had failed to reveal the parasite. The patient was given a course of neostibosan and made an uneventful recovery.

ADLER, S., TCHERNOMORETZ, I. & BER, M. The Action of some Aromatic Diamidines on Cultures of *Leishmania donovani*. *Ann Trop Med & Parasit* 1945 May 31 v 39 No. 1 14-19

The authors have tested a series of aromatic diamidines on cultures of *Leishmania donovani* with the object of correlating the results, if possible with those obtained in the treatment of experimentally infected hamsters as previously reported [this *Bulletin*, 1940 v 37 775 and 1942, v 39 748]. It was found that in the highest concentration of each drug which still permits survival and retention of motility of flagellates there is a definite inhibition and even abolition of the capacity to multiply. For each compound there is a fairly well defined maximum concentration which permits 90 to 100 per cent. of normal growth. There is no sharp end-point at which all the flagellates disappear. The two most effective drugs tested were 4,4'-diamidino diphenoxy propane [propamidine] and 4,4'-diamidino diphenoxy pentane [pentamidine] both of which have been shown to be inferior to 4,4'-diamidino stilbene [stilbamidine] in tests on hamsters. There is thus no correlation between the results of *in vitro* and *in vivo* tests though the four least effective compounds were in this position in both tests.

FEVERS OF THE TYPHUS GROUP

SYLLA, A. Fleckfieberbeobachtungen. [Observations on Typhus Fever] *Deut. Wochenschr.* 1944 June v 9 No. 6 263-72.

A clear and detailed description is given of the clinical features of typhus fever as observed by the author during the recent war. Numerous references are also made to papers already reviewed in this *Bulletin*.

Some points from the paper are as follows (the figures in brackets show the percentage incidence and when two figures are enclosed in one pair of brackets the first shows the incidence in cases with recovery the second refers to fatal cases).

The disease on the whole was mild the average fatality rate was about 6-7 per cent but there was a wide range of variation in different groups of cases the extremes ranged from 1 to 15 per cent Even during the same outbreak there might be great differences in severity at various stages of the epidemic. The incubation period ranged from 8 to 21 days. During the first three days the temperature fell to normal in some cases for a few hours then rose to about 39°C and persisted at that level The fever curve was usually of the continued type (89.3) but in some cases was remittent or intermittent A pseudo-crisis occurred in 12 per cent of the cases about the 10th day The termination was by lysis (70) or crisis (30) an after fever occurred in many cases (25-6)

The rash might be pale and scanty (50) dark red (38.7) or of irregular types such as papular scarlatiniform morbilliform etc. (4.5) petechiae were often seen (23 and 55) Pulmonary manifestations were bronchitis (50 and 65) bronchopneumonia (7 and 25.8) and lobar pneumonia (1.3 and 11) Cardio-vascular failure was attributed to myocarditis (10 and 49.7) or peripheral circulatory disturbance (13.8 and 86.5) Venous thrombosis was not common (1.6 and 3.7) gangrene was rare amputation of a limb was needed in only one case. Arterial spasm (1.3) rather than arterial thrombosis occurred in a few cases in the limbs.

The nervous manifestations were delirium (24.8 and 73.6) various psychoses especially mania and suicidal tendencies (6.3 and 34.9) tonic clonic spasms (1.1 and 24.8) nerve pareses (0.8 and 9.2) hardness of hearing (26) sometimes associated with inflammation of the middle ear (3.8)

Diagnostic importance was attached to the prolongation of the latent period of dermatographism

Diarrhoea (17) enlargement of the liver (5) icterus (1.1) and enlargement of the spleen (58) were observed in the stated percentages. Slight albuminuria was usual the urine often contained red and white blood cells and cylindrical casts a true nephritis occurred in 10.8 per cent of the cases.

The blood picture was very varied leucocytosis occurred in about half of the cases leucopenia was not infrequent. The leucocytic index always showed a shift to the left Septic complications were few

The chief findings at autopsies were myocarditis slight (39.2) or severe (33) pneumonic complications (47) swelling of the kidneys (100) splenic enlargement (98) and oedema of the brain (100) No enthusiasm is shown for some of the special treatments that have been vaunted by some other German observers warm baths sulphonamides and atabrin were regarded as of doubtful value. Strophanthin caffeine and adrenaline were found useful glucose transfusions sometimes in concentrated form were occasionally needed. The general treatment was on orthodox lines.

CLAUS G. Über Mittelohr und Warzenfortsatzentzündung bei Fleckfieber
[Middle-Ear and Mastoid Inflammation in Typhus Fever] *Deut. Militärarzt*
1944 Aug. v. 9 No. 8 366-70 2 figs. [12 refs.]

Four cases are described in which pyogenic complication affected the middle ear with extension to the mastoid process. Although the condition is not common it is not so rare as is generally supposed and it deserves attention because of the danger of extension to the lateral sinus. Two exceptionally clear X ray photographs illustrate the paper and a description is given of the operative technique.

ROGERS, R. Physiologisch-chemische Untersuchungen bei Fleckfieberkranken. [Biochemical Investigations in Typhus.] *Dtsch. Med. Wochenschr.* 1944 Aug., v 9 No. 8 37-39 1 fig

An investigation of the non-protein nitrogen, sugar and chloride concentrations of the blood and blood serum in typhus fever

RECHET, C. Notes sur le typhus exanthématique observé à Bochenwald. [Typhus in the Buchenwald Concentration Camp.] *Bull. et Mém. Soc. Méd. Hôp. de Paris* 1943 Nos 15/16, 183-7

ECKE, W. Proteus-OV19-Agglutination und Rickettsien-Agglutination bei Fleckfieberimpfungsgenossen [Proteus OV19 and Rickettsia Agglutination Reactions in Persons Protected by Typhus Vaccines.] *Dtsch. Med. Wochenschr.* 1944 Apr v 9 No. 4 188-91 [10 refs.]

The titres observed in groups of persons vaccinated (presumably recently except in the group vaccinated 4-6 months previously) with Weigl's loose vaccine or a Cox type vaccine were as shown in the table. With regard to the first group of 130 it is stated that 100 had received Weigl's vaccine and 21 the Cox type vaccine—positive reactions were relatively much more numerous in the latter sub-group but no details are given.

Well-Felix Titres.

	Negative	1-50	1-100	1-200	1-400
Among 130 vaccinated	51	31	31	15	2
Among 49 vaccinated 4-6 months previously	34	7	4	4	0

Rickettsia-Agglutination Titres

	Neg	1-20	1-40	1-80	1-160	1-320	1-640	1-1,280
Among 100 vaccinated	2	3	9	41	19	13	12	1

John W D Meyer

SHOCKLEY, J. S. Bedside Typhus Diagnosis. *J. Roy. Egyptian Med. Ass.* 1945 May v 28 No. 5 231-45.

The introductory "blurb" states that the method described is "A quick and simple variation of the Well-Felix reaction giving positive results much earlier than the original test in 50 per cent. of the cases."

The test is a slight variant of a well-known slide test. A droplet of finger blood is mixed with a drop of plain water—a drop of a thick suspension of *Proteus* O19 stained with methylene blue is added and stirred in for 30-60 seconds. The method of preparing the suspension is described. The growth from 10 agar 20-hours slope cultures is mixed with 10 cc. distilled water and two drops of formalin are added. After filtering the suspension through a thin layer of cotton, 0.2 cc. German Loeffler's blue solution is added—the mixture is well shaken and kept in the incubator for a day or two being shaken twice daily during the process. It is again filtered through cotton and another drop of formalin is added.

The degree of dilution of the blood on the slide is 1-7

It is claimed that the use of water and formalin abolishes the agglutination inhibitory zone of the serum that the water prevents coagulation and haemolyses the red corpuscles and that false positives due to natural agglutinins do not occur

From the table showing the results of comparative tests it appears that all titres below 1-125 with the standard Weil Felix test are shown as negative results This arbitrary elimination of weak positives must be taken into account in estimating the significance of the findings *John W D Megaw*

LORENTZ F H Der Trockenfolientest zur raschen Erkennung des Fleckfiebers [The Dry-Leaf Test for the Rapid Diagnosis of Typhus Fever] *Med Ztschr* 1945 Jan. v 1 No 4 128-30 6 figs.

The author describes the results obtained in a large series of tests carried out by the method introduced by EYER and BRIX [see this *Bulletin* 1944 v 41 23] The only special requisite for the test is a supply of ready prepared slips of paper on each of which a drop of stained suspension of *Proteus O\19* has been dried but details of the technique will be of interest only to workers engaged in testing the various rapid modifications of the Weil Felix reaction.

From the present paper it is evident that the method demands a good deal of practice the first series of 100 tests yielded a number of anomalous results and so have been discarded from the final analysis which deals with a series of 1 000 consecutive tests and compares the findings with those obtained by means of the standard reaction

A general degree of agreement is claimed between the two tests and broadly speaking the relationship between the reactions was as follows Negative reactions correspond to negative Weil Felix responses weakly positive reactions (\pm) correspond to titres of about 1-200 positive reactions (+) to titres of about 1-600 and the two highest grades of reaction (++) and (+++) to titres of 1-3 000 and over

The table shows that there was a good deal of variation from this standard for example among 106 negative reactions with the rapid test there were 52 in which the Weil-Felix titre was \pm 1-100 or +1-100

Among 378 weakly positive reactions the Weil Felix titres were \pm 1-100 in 73 +1-100 in 57 +1-200 in 176 +1-400 in 61 +1-800 in 9 +1-1600 in 2. *John W D Megaw*

CLAVERO G & GALLARDO F P Grounds Intradermic Test in Typhus Fever Infection Personal Observations, Techniques, and possible Applications *Bull Health Organisation* (League of Nations) 1943/44 v 10 No 4 700-21 8 figs on 4 pls. [30 refs.]

The original article was reviewed in this *Bulletin* 1943 v 40 530

SCHMIDT W Erfahrungen zur Therapie des Fleckfiebers. [Experiences in the Therapy of Typhus Fever] *Deut Militärarz* 1944 June v 9 No 6 273-6 1 fig

The author claims to have saved a number of lives by injections of insulin—which in severe cases was given up to the point of causing hypoglycaemia—followed by the administration of glucose preferably by the mouth but intravenously when necessary The dosage of insulin when possible was based on blood sugar estimates during the fasting period. Comatose patients were given up to 20-30 gm glucose intravenously every day

The fatality rate in a group of patients treated by insulin and glucose when necessary was 6.3 per cent. In another group stated to be comparable in all other respects, the rate was 11.9 per cent., but no information is given with regard to the size of the two groups or the other circumstances which justified a statistical comparison of the results.

John W. D. Meyer

SCHÖNBRUNNER, E. Strophanthin und Digitalistherapie des Fleckfiebers [Strophanthin and Digitalis Therapy in Typhus Fever] *Deut. Med. Woch.* 1944 Sept., v. 9 No. 9 412-15 4 figs. [27 refs.]

Full details are given of an exceptionally severe case of typhus fever in which the pulse rate rose to 160 on the 14th day and continued to rise in spite of "strophanthin-glucose thrice daily." On the 16th day the rate was 170-190 and frequent doses of strophanthin were given intravenously amounting in all to 1.25 mgm. The rate rapidly fell to 100 and there was a great improvement in the patient's condition.

The strophanthin-effect lasted a short time and in spite of further injections the rate rose as high as before. Digitalis was given in the form of 2 cc. "Digipur" every six hours and the rate fell promptly to 100-140. By the 26th day the improvement was so great that the dose of digitalis was given only once daily.

The author states that there are practically no contraindications to the "strophanthin (digitalis) treatment in typhus fever whether the circulatory failure is due to myocarditis or to damage to the vasomotor centres.

In the case described the reductions in the pulse rate were due to the production of a 2-1 heart block, as is shown by the electrocardiograms.

John W. D. Meyer

GRUBEL, W. Ueber die Fleckfieber-Rekonvaleszenz mit besonderer Berücksichtigung des Kreislaufes [Convalescence in Typhus Fever with special reference to the Circulatory System.] *Vinck. Med. Woch.* 1944 Aug 25, v. 91 Nos. 33/34 428-9.

The author begins by referring to the expansion of the German "Lebensraum" to the East as being responsible for a renewed interest in typhus fever.

The present study deals with 119 convalescent patients aged 19-43 years who were kept under observation till about three months after the onset of the illness. Careful records were kept of the results of simple tests of circulatory efficiency and an analysis is given of the findings before and after exercise tolerance tests carried out at various stages of convalescence. According to the criteria adopted by the author for estimating the significance of these tests it was found that four weeks after the onset of the illness 81.5 per cent. of the patients had a definite degree of circulatory insufficiency: 15.1 per cent. had circulatory lability and 3.4 per cent. gave normal responses to the test. Twelve weeks after the onset the corresponding figures were 31.9 per cent., 51.3 per cent. and 16.8 per cent. Abnormal increases, after exercise in the pulse and respiration rates and in the pulse pressure were regarded as reliable indications of circulatory disturbances.

Electrocardiographic examinations were made in 89 cases. In 13 of these there was evidence of coronary insufficiency or myocardial damage but at the end of four months only four patients showed any abnormality. Permanent myocardial damage was believed to be of rare occurrence. Among patients observed between the 4th and 12th weeks the lymphocyte count was increased in 63 per cent. and the eosinophile count in 46 per cent.

The blood-sedimentation rate remained high for a long time in most of the cases.

The complications observed among the patients studied were acute glomerulonephritis in one patient this occurred on the 7th day and recovery was complete by the end of seven weeks slight joint rheumatism in two patients urticaria in one and angioneurotic oedema in one These complications had no obvious effect on the circulatory system *John W D Megaw*

NILKA W A Histological Study of the Lungs of Mice Infected with Typhus Rickettsiae. *J Path & Bact* 1945 July v 57 No 3 317-24 12 figs on 4 pls.

The author describes the histology of the lungs of mice inoculated intranasally with murine or epidemic strains of typhus rickettsiae three of the former and seven of the latter strains were used. The methods of preparing the infecting suspensions and of fixing and staining the lungs are described. The following improved method of staining was employed.

Fix lung sections in 10 per cent neutral formol stain in 1 10 000 aqueous methyl violet $\frac{1}{2}$ -1 hour differentiate in weak acetic acid (2 drops to 100 cc water) until the cytoplasm is unstained counterstain with 1 10 000 aqueous metanil yellow a few seconds acetone xylol mount in Xam (Gurr) or DPX4 mounting medium (Media Mounting Centre)

The paper is illustrated by 12 excellent photomicrographs Large numbers of mice were employed In those allowed to die of the disease there was complete consolidation of the lungs often with a small amount of pleural exudate in the mice that were sacrificed various stages of congestion and consolidation were observed In the congested areas all the blood vessels especially the alveolar capillaries were dilated and the epithelial cells of the alveoli were swollen.

Consolidation was due either to inflammatory oedema or to swelling of the epithelium and packing of the lumen with desquamated alveolar cells and with leucocytes. In many places the vessels and bronchioles were seen to be surrounded by thick cuffs composed chiefly of monocytes.

The usual types of rickettsiae were seen some were extracellular and occurred either in discrete form in clumps in large groups or in masses in the alveoli. Intracellular rickettsiae were most abundant in the alveolar cells whose cytoplasm sometimes was completely packed with cocco-bacilli form or rod shaped organisms in other cells there were masses of granular forms. The endothelial cells of the vessels seldom contained rickettsiae this finding is in sharp contrast with the special invasion of these cells described as occurring in guineapigs inoculated intraperitoneally

Lungs infected by murine rickettsiae were on the average much richer in the organisms than those infected by epidemic strains otherwise the changes caused by the two types of rickettsiae were similar

Secondary infections were surprisingly rare whether or not the mice had been treated by sulphonamides. It is suggested that the rickettsiae inhibit the growth of bacteria *John W D Megaw*

PHILIP C B & KOHL G M Studies on Tsutsugamushi Disease (Scrub Typhus, Mite-borne Typhus) in New Guinea and Adjacent Islands. Tsutsugamushi Disease with High Endemicity on a Small South Sea Island. *Amer J Hyg* 1945 Sept v 42 No 2 195-203 4 figs.

This study was carried out under the auspices of the U.S.A Typhus Commission. The authors investigated an outbreak of tsutsugamushi disease which occurred on South Bat Island, situated about 60 miles south of the Admiralty Islands and having its total area of about 46 acres completely

covered by cocoanut palms under which sparse grass and scattered under growth grow. Normally the island is uninhabited except for periodic visits by natives for harvesting the coconuts.

The island swarms with rats—*Rattus coscolor brevis*—there were 15 pairs of the domestic type which lived in wild conditions. Fruit bats and several species of birds were also found.

The only biting insect that was detected was *Aedes scutellaris*. Large numbers of larval mites were found on the rats—these were *Trombicula deliensis* Walch 1923 which H. Womersley has now reported to the authors to be identical with *T. walchi* Womersley and Heatlip 1943. *Schöngastia pusilla* Womersley 1944 was abundant in boot collections but was not found on any of the animals or birds that were examined. It was probably responsible for scrub itch which occurred among the occupying troops. A few specimens of a new species of *Neoschöngastia* were found on a bird, the ground-living rail, *Rallus philippensis*. No other species of mite was found.

Each of five pools of triturated *T. deliensis* from the rats was inoculated intraperitoneally into four white mice and one very large pool of the same larval mites was inoculated into eight mice. Most of the mice died, either within the first two days or later of intercurrent infection so that by the end of 15 days only three mice survived, one from each of three pools. From each surviving mouse a virulent strain of *Rickettsia orientalis* was isolated, one strain which was transmitted through 29 mouse passages killed the animals on the average in 5½ days. It killed nine of ten inoculated guinea-pigs.

Among 41 white persons who camped on the island for varying periods between the end of February and the middle of April 1944 and who could be traced afterwards there were 26 definite cases of tsutsugamushi disease. There were two deaths, and most of the patients were seriously ill.

A minority of the campers had slept in hammocks and escaped infection; the majority had slept on cots placed on wooden floors raised from the ground.

The incidence of some of the chief features of the disease is shown in a table. Among the 24 for whom reasonably complete information was available the duration of the fever ranged from 12 to 23 days except for one patient in whose case it lasted 8 days. An eschar was seen in 14 cases; in 8 it was not detected and for the remaining two the information was doubtful. A rash was seen in 11 cases. The results of the Weil-Felix test (*Proteus* OXK) are given for 19 patients; in 8 it was negative but the test was not made till the 35th to the 47th day. In the others the titre ranged from 1-80 to 1-160 or over; most of the tests were made after the 20th day.

This is the first time that *T. deliensis* has been found infected in natural conditions; the only other species hitherto found naturally infected are *T. amushi* in Japan, and *T. fleischeri* in New Guinea.

The high degree of prevalence and virulence of the infection among mites in the island is regarded as being due to the great density of the rat population and the consequent opportunities that exist for rapidly recurring transmissions from rat to mite and from mite to rat.

John W. D. Megaw

KLEIN, H. S. An Epidemic of Scrub Typhus. *J. Roy Army Med Corps* 1945 Oct., v. 85 No. 4 187-90.

The author describes the clinical features of an outbreak of scrub typhus which occurred in the months of October, November and December 1944 in the Chin Hills of North Burma. Although 225 patients were admitted to hospital during the period the present description deals only with 41 cases among British soldiers; the other cases among Indian troops, are said to have been essentially similar in type.

The incubation period ranged from 4 to 14 days the onset was sudden in about two-thirds of the cases in the others there were feverish headache and malaise for two or three days before the onset In the early stages of the illness the disease closely resembled louse-borne typhus by the third day the patients were seriously ill extreme apprehension was a conspicuous feature and it is stated that dread of the disease was universal among the British troops most of whom preferred the Japs This psychological factor (which has been emphasized by several observers in the Pacific area) was suspected of contributing to the high fatality rate among the British patients of whom five (about 12 per cent.) died whereas only seven deaths (3.8 per cent.) occurred among the 184 Indian patients.

An eschar was seen in 34 per cent of the patients generalized lymphadenitis occurred in all the cases but lymphangitis was never seen All but one of the patients had a rash of a dull red colour it was macular in 30 cases maculo-papular in seven papular in two and morbilliform in one The rash appeared first on the trunk and soon extended to the arms legs and face the palms and soles were never affected.

In all but two of the patients who recovered the termination was by lysis In four of the fatal cases there was a sudden drop in the temperature with collapse followed by a terminal rise just before death which occurred on the 13th 14th 15th and 21st days.

In four cases malaria parasites were found these were benign tertian in three and malignant tertian in one

The chief complications were as follows —Bronchitis occurred in 32 cases and pulmonary infarction in seven The indications of infarction in four of these were sudden pain in the chest cough and haemoptysis in three there were pain and cough without haemoptysis and in one case which was diagnosed after death the only symptom was epigastric pain Lobar pneumonia occurred in one case in which it was the chief cause of death Pharyngitis with laryngitis and tonsillitis was present in four cases Half of the patients had temporary deafness five had retention of urine and five had severe mental symptoms—delusions hallucinations or delirium—but all made good recoveries There was one case of femoral thrombosis also with recovery

The changes that were found after death in all the fatal cases were oedema and congestion of the brain small pale and toxic looking heart slight hypostatic congestion of the lungs and enlargement of the intrathoracic lymph glands There was mononuclear infiltration between the muscle fibres of the heart and slight decrease in the adrenal cortex

No benefit was observed from the use of penicillin sulphonamides were administered to all patients who had chest complications given also after catheterization they were believed to have prevented secondary urinary infection

A fluid intake of 8 to 10 pints was aimed at in spite of the cool situation of the hospital at a height of 5 000 feet Twenty grains of sodium chloride were added to each pint of liquid The diet included such articles as bread biscuits and tinned fruits 2 400 calories were given daily Lumbar puncture caused dramatic improvement in four semi-comatose patients whose cerebrospinal fluid pressure was high but it failed in one case in which the pressure was low

John W D Megaw

ANDREW R. A Note on the Incubation Period of Scrub Typhus and its Correlation with Clinical Severity *Med J Australia* 1945 Sept 15 \ 2 No 11 335-6

In a group of cases of scrub typhus in North Queensland it was possible to fix the incubation period with a considerable degree of reliability Among 21

cases 10 were classed as being severe (7) very severe (2) or fatal (1) and the incubation period was 12 days in all of them. Among 10 cases classed as moderate (3) mild (4) or very mild (3) there were five in which the period was 15-17 days, in three it was 13 days and in two it was 12 days. In one sub-clinical case it was 18 days.

Weil-Felix tests, carried out retrospectively on 25 other soldiers who had been exposed to similar risk, revealed that two of them had high titre reactions with *Proctos OVK* on the 28th or 29th day after exposure to risk—one of these soldiers gave a history of chilly feeling, headache and myalgia, lasting 12 days and starting 13 days after exposure—his titre was 1-8 000—the other soldier had only headache and coryza, which lasted three days after a presumed incubation period of 18 days—his titre was 1-1 600.

It is stated that 55 cases of scrub typhus, contracted at the same time were treated elsewhere and that only one death occurred in the whole outbreak, in which at least 78 persons were attacked. *John W D McGraw*

DAKE L. R. Eye and Ear Sequelae of Scrub Typhus Fever *Bull U.S. Army Med. Dept.* 1945 Nov v 4 No 5 534-7

Among 50 patients seen at a general hospital convalescent (four to six weeks average six weeks) from scrub typhus fever 50 per cent. of them had noticeable eye symptoms during the various stages of the disease which proved to be transient and of minor importance. No permanent loss of visual acuity was found to be associated with this disease. In 98 per cent. of these eyes there were some abnormal subjective retinal findings, consisting of enlargement of the blind spots, contraction of the visual fields, and scotomata. The average size of all of the blind spots was 30 by 40 cm., and the largest 38 by 60 cm. There were 7 per cent. of field contractions, and 10 per cent. had scotomata, the largest being one-eighth of the visual field.

"Minor non-specific involvement of the cochlear system was found in only 11 per cent. of the ears at this stage of convalescence although by history 78 per cent. of the ears had had hearing loss or tinnitus. All 50 patients had normal hearing with conversational tones. Involvement of the vestibular system was indicated in 59 per cent. of the ears with caloric stimulation. The of production and chronicity are not definitely known.

"TEXAS" J. M. Field Investigations Pertinent to Bulb's Fever The Lone Star Tick, *Amblyomma americanum* (Linnaeus, 1758). Notes and Observations from Camp Bulb's, Texas. *Texas Reports on Biol & Med.* 1945 v 3 No. 2, 204-28 3 figs. [17 refs.]

This abstract is supplementary to the one dealing with the author's preliminary note on the present investigations [see this *Bulletin* 1945 v 42, 789]. Full details are given of an exhaustive survey of *Amblyomma americanum* in the Camp Bulb's area from June 8 to October 1 1944. This tick has already been found infected with Rocky Mountain spotted fever American Q fever and tularemia in Texas. The chief object of the survey was to obtain large numbers of the tick for the further investigation of Bulb's fever with regard to which the author states that "it is quite likely that this disease is rickettsial" and that it is "a new rickettsial disease entity" [The latter statement will be considered by some workers as too dogmatic.]

More than 50 000 specimens of various stages of the tick were collected in the area where it forms more than 85 per cent. of the total tick population, and where it is exceedingly abundant owing to the very large numbers of animals and birds which live in closely preserved conditions. In one case 294 of the

ticks mostly adults were found on a soldier on the head of one deer 910 adults were found and on the head of another there were 1 160 nymphs larval forms were often too numerous to be counted. On occasions as many as one to three thousand larvae but very few adults were found on a fox a jack rabbit and a quail Under a single small juniper tree four collectors picked up 4 086 adults from the thick litter of needle leaves on the ground in the course of a single day

The collection of unfed ticks by dragging the ground with a sheet of white flannel was found unsatisfactory the plan adopted was to search for spots where the ticks were plentiful a collector seated on the ground would often attract as many ticks as could be dealt with Instead of using a cork for the collecting tube it was found better to tie a sheet of thin rubber obtained from a discarded surgical glove over the mouth of the tube and to cut a small slit in the rubber through which the ticks could be inserted by forceps. On completing the collection the rubber sheet was replaced by a plug of cotton wool.

The methods of collecting fed ticks from animals are described. Tables in the paper give full details of the infestation rates of the various hosts at different seasons Every one of the 15 species of mammals examined was infested by ticks the numbers on small rodents and on the armadillo were negligible. The dominant host of adult ticks was the deer which also harboured large numbers of nymphs and larvae The rabbit fox raccoon, skunk and birds living on the ground or in thickets were heavily infested by nymphs and larvae. Among the birds examined, 32 species were infested and 14 were non infested.

The period of human infestation began in late February the rate increased steadily till the end of May declined slowly till the end of July and then fell rapidly till the middle of August From October to January tick activity was negligible.

[Entomologists who have occasion to carry out tick surveys will find a great deal of useful information in the paper]

DOERR W Morphologische Veränderungen bei Wolhynischem Fieber [The Morbid Anatomy of Trench Fever] *Münch med Woch* 1944 Sept 22 v 91 Nos. 35/38 456-8 [10 refs.]

The changes described were found at the autopsy of a German soldier who killed himself by shooting on being discharged to duty from a hospital where he had been under treatment for two months for an illness diagnosed by competent physicians as trench fever About seven months before this illness he had suffered from a moderately severe attack of typhus fever and the changes observed after death could not be distinguished from those commonly resulting from typhus fever The author himself admits that there is some doubt whether the lesions were due to typhus fever or trench fever but he argues at some length in support of the view that trench fever was the cause

John W D Megaw

STÜHMER A Das wolhynische Periodische Fieber [Wolhynian "Periodic Fever (Trench Fever)] *Münch med Woch* 1944 Aug 11 v 91 Nos. 31/32 401-3 1 chart. [11 refs.]

In 1916 the author published an article on A New War Disease Resembling Relapsing Fever In the present paper he describes an attack from which he suffered in 1916 The incubation period could be definitely fixed at 24-25 days. After three short spells of fever with a periodicity of about 7 days there was a long period in which only an occasional slight rise of temperature occurred. From the 12th to the 16th week fever of the undulant type occurred

with a periodicity of about 7 days. The illness lasted for three more weeks, during which there was hardly any fever but there were three spells of pronounced tachycardia.

Recurring bouts of diarrhoea, great weakness and severe shin-bone pains were the other chief features.

John W D Megaw

DAVIDS B Jr Beobachtung einer Netzhautblutung bei Wolhynischem Fieber [Retinal Haemorrhage in Trench Fever] *Deut med Woch* 1944 Aug 4 v 70 No. 31/32, 450-51 2 charts.

A German soldier was admitted to hospital after having been in several other hospitals during the preceding month suffering from pain in the head, legs and especially the shins a provisional diagnosis of Wolhynian fever [trench fever] had been made.

On admission he complained of poor vision, which he had first noticed while writing a letter about three weeks before. About a week before admission the sight of his left eye had become very bad.

On examination a large preretinal haemorrhage was seen the rest of the retina and the bloodvessels being apparently normal. It gradually decreased in size during the following week and he was then transferred from the hospital.

He had no fever on admission nor afterwards, but during the previous month the temperature chart showed a curve resembling that of five-day fever [trench fever]. The differential diagnosis from typhus is discussed the agglutination test with *Proteus OX19* was negative and there was no rash, while the appearance of the retina did not resemble the condition seen in typhus. As both his parents had died of apoplexy at about 70 years of age the author thinks that there may have been a constitutional tendency to vascular disease.

J F Corson

RAETTING H. Die Pyryferbehandlung des Fünftagefiebers. [The Treatment of Trench Fever by Pyryfer, *Med Ztschr* 1944 Dec. v 1 No. 3 101-2, 5 charts. [45 refs.]

The author states that his experience in the treatment of 50 patients with pyryfer " [a proprietary colon bacillus vaccine for producing artificial pyrexia] confirms the favourable opinions expressed by RHEMDORF and other observers. He found that definite benefit resulted from a single injection in one-third of the cases, provided that the drug was administered during a febrile paroxysm. Repeated doses at intervals of two days gave no better results than a single injection.

The rationale of the treatment is believed by Rhemdorf to be " an almost specific activation of the processes " [presumably of the immunizing mechanism].

No mention is made of the use of controls [see also this *Bulletin* 1945 v 42, 31].

YELLOW FEVER.

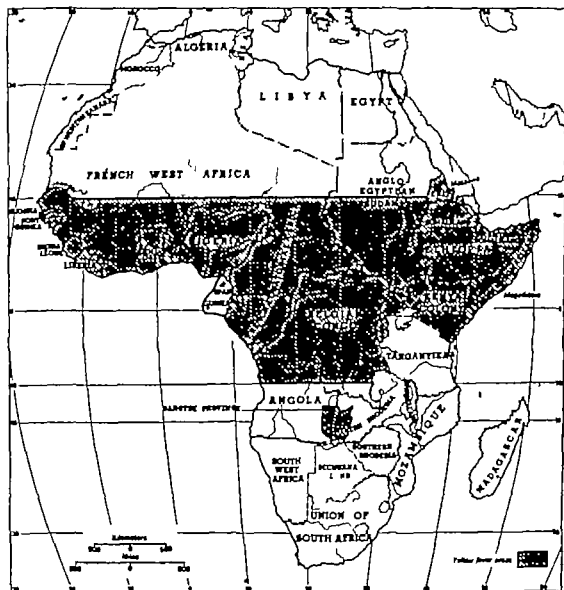

EPIDEMIOLOGICAL INFORMATION BULL. (UNRRA Health Division.) Washington, D.C. 1945 Sept. 30 v 1 No. 18 687-92, 2 maps. Third Report of the Expert Commission on Quarantine [STOCK, P G Chairman]

The delimitation of certain parts of Africa and the Western Hemisphere as endemic areas of yellow fever for quarantine purposes, recommended by the

Expert Commission on Quarantine of UNRRA was adopted by the Standing Technical Committee on Health on 11th December 1944 since then the Commission has advised that certain additional areas should be included in the endemic zones

In Africa the additional area is the Barotsse Province of Northern Rhodesia in the Western Hemisphere the occurrence of cases of yellow fever in Venezuela and in the States of Minas Gerais and Goyaz in Brazil has led the Commission to recommend an alteration in the previous definition of the delineated areas

The endemic areas are shown in the accompanying maps in South America the western boundary of the endemic area in Colombia and Peru passes along the eastern slopes of the Central Cordillera and the Andes Mountains at a height of 2,000 metres to the boundaries of Argentina and Bolivia.

African Yellow Fever Area delineated by Expert Commission on Quarantine

J. F. CORSON

DE PAULA SOUZA G. H. Yellow Fever Areas. *Epidemiological Information Bull.* (UNRRA Health Division) Washington, D.C. 1945 Sept. 30 v 1 No 16 663-701 [10 refs.]

Under the International Sanitary Convention of Aerial Navigation 1944 the nations concerned agreed to determine whether yellow fever existed in their territories and the Expert Commission on Quarantine of UNRRA defined the endemic areas of the disease i.e. where yellow fever exists in a

form recognizable clinically, biologically or pathologically these boundaries were specified for Africa and South America respectively [see above]

The mouse protection test, viscerotomy, and the examination of animal and insect hosts for yellow fever virus were the methods used. The last of these three methods caused the Ilheus and Itabuna districts in Brazil to be included.

The position is subject to revision from time to time and an area may cease to be considered endemic if satisfactory evidence regarding risk of infection and control of *Aedes aegypti* is furnished.

The Pan American Sanitary Bureau suggested to the Expert Commission that three classes of areas should be distinguished:—(1) Endemic areas where cases have occurred and where conditions favour its recurrence; (2) areas where the risk of becoming infected exists; (3) potentially infectible areas where an *Aedes aegypti* index (i.e. the percentage of houses with breeding foci of *Aedes aegypti*) of 0.4 or higher exists.

The National Department of Health of Brazil pointed out that the infected areas in Brazil varied in character and suggested in detail certain modifications and exceptions.

More information about endemic areas is available for South America than for Africa. In Brazil in 1936 there were 1,559 viscerotomy posts and 32,031 liver samples were examined. In South America an *aegypti* index of 0.4 and less is attainable while in Africa a goal of 1 per cent is regarded as a good first step.

In the Western Hemisphere the Central American countries west of the Canal Zone are no longer endemic areas and the same applies to Mexico and the Caribbean islands. In eastern Panama the endemic area approaches to within 50 miles of the Canal Zone.

No urban outbreak transmitted by *A. aegypti* has occurred in America since 1933 though *aegypti* transmitted yellow fever has often followed jungle yellow fever in Brazil, Bolivia and Colombia between 1934 and 1938 and once in 1942 in the Acre territory in Brazil. The risk of new outbreaks of *aegypti* transmitted or urban-rural yellow fever in South America is now much reduced. A campaign against the mosquito is yielding good results. In 1944 effective work was carried out in 44,859 localities with the result that 42,946 were completely freed. *Aedes aegypti* has been eradicated from eight States and all ports in Bolivia, Colombia, Ecuador, Paraguay and Brazil have an *aegypti* index of close to or actually zero.

Yellow fever still continues in endemic form or as wandering epidemics shifting from one area to another in vast jungle areas. No human case has been found around Villavicencio, Colombia, since 1938 and from protection tests on local wild animals it is thought that active virus no longer exists there. Similar shifting of areas occurred in Brazil. In 1945 an outbreak in the States of Goyaz and Minas Gerais after quiescence for three years caused 101 deaths in the first few months. In July 1945 18 deaths occurred in Venezuela and 14 in Colombia while in May 1945 there were six deaths in Peru and two in Bolivia, east of the Andes in both countries.

In Africa knowledge is based chiefly on surveys. In the western area which extends to the eastern border of Nigeria, *Aedes aegypti* was the vector in urban outbreaks. In the eastern area there is a zone of high incidence of human immunity situated between latitudes 3 and 8 N and extending from the French Cameroons across French Equatorial Africa into the Anglo-Egyptian Sudan as far as Rumbeck. North and south of this zone there is a lower incidence of immunity. The Barotze Province of Northern Rhodesia is an inland endemic area.

For quarantine purposes endemic areas are extended to the Indian Ocean owing to the danger of eastward spread and the risk to India.

Extensive vaccination of persons exposed to jungle yellow fever anti-mosquito measures and prompt information of jungle infection, should make the defence against yellow fever complete.

DENGUE.

BOEHMARDT H. Ist das Bessarabienfieber eine neue Krankheit? [Is Bessarabia Fever a New Disease?] *Med Ztschr* 1945 Jan. v 1 No 4 126-8. [15 refs.]

The author had described a short two-phase fever occurring in Bessarabia as a hitherto unknown disease [see this *Bulletin* 1943 v 40 839]. He now replies at length to the adverse criticism of this view by MARCOWSKY [see this *Bulletin* 1944 v 41 988]. He makes out a strong case against the suggestion that the disease may have been trench fever or a fever of the typhoid group but he admits that serious consideration must be given to the possibility of its being an aberrant form of sandfly fever.

[The controversy over this and other new short fevers in South Eastern Europe is reminiscent of the many discussions relating to short fevers in tropical countries about 25 years ago. In both cases the diseases probably belong to the dengue-sandfly fever group.]

PLAGUE.

MACRAT DICK, J. A Brief Report on Twenty-Six Cases of Bubonic Plague with the Results of Treatment. *J Roy Army Med Corps* 1945 Sept., v 85 No. 3 105-8.

This report adds one more to the publications on the use of sulphonamide drugs in plague. Its purpose is to give the results of the treatment and to emphasize the desirability of early diagnosis and adequate treatment. Under these circumstances it is maintained that the mortality can be expected to be low. The 26 cases in this series are all set out in detailed tabular form, individually with the precise treatment employed. This averaged 30 to 45 gm. of sulphapyridine per case the sulphapyridine being combined with antiplague serum in 18 of the cases. The author insists that rest in bed should be strictly enforced as in diphtheria, and the need for this appears to be exemplified by the occurrence of two sudden and unexpected deaths in patients who appeared to be out of danger. He is convinced of the value of sulphapyridine in plague given either alone or in combination with antiplague serum. It is interesting to note that gland puncture becomes negative after 24 hours of sulphapyridine therapy even when a positive result has previously been obtained.

CHOLERA.

STOWMAN K. International Quarantine Diseases. I. Cholera. *Epidemiological Information Bull* (UNRRA Health Division.) Washington, D.C. 1945 Aug 15 v 1 No 13, 551-61

An account of the distribution of cholera during the present century

GRABAR P & GALLUT J Recherches immunochimiques sur le vibron cholérique IV Essais de purification de la substance hypothermisante de la toxine cholérique [Hypothermy producing Constituent of Cholera Toxin Its Purification] *Ann Inst Pasteur* 1945 Sept-Oct v 71 Nos 9-10 321-6

The characters of the two constituents of cholera toxin were defined in a previous communication [this *Bulletin* 1945 v 42 807] Production of hypothermy and small molecular dimensions were the most notable of the properties found for the second constituent purification of which is dealt with in this article under the headings dimension of the molecule antigenic power and chemical fractionation. A new technique is presented for its extraction of which the detail is as follows —Crude toxin of pH about 5.6 is precipitated with 1.5 ammonia which occurs at about pH 8.6 This precipitate is washed several times with N/100 disodium carbonate until the supernatant fluid gives no precipitate with antilipidic serum It is then totally dissolved by N/10 hydrochloric acid at pH 3.5 In these attempts at purification the following characters have been established for the hypothermy fraction of the cholera toxin It can pass cellophane membranes has no antigenic power is not precipitated by trichloroacetic acid nor by sodium tungstate Therefore it is probably not proteid (as the authors previously thought) it is probably a relatively small molecule thermolabile and liable to be carried down in the course of different precipitations.

YACOB M & CHAUDHRI J R. A Note on the Presence of 'O' Agglutinins in the Blood of Cholera Patients. *Indian Med Gaz* 1945 June v 80 No 6 291-3

Agglutinins may appear in cholera cases by the second day and are well marked by the sixth day Their titre is not very high and the O agglutinins varied in the present series from 1 in 50 to 1 in 150 Little or no work seems to have been done previously on the persistence of these agglutinins and that is the main object of the present enquiry A knowledge of this point would be useful to the epidemiologist in case it were necessary to conduct a late investigation of an outbreak of cholera in any locality Thirty-seven cases were collected with positive results in 13 and with the possibility of duration up to three and a half months possibly more

W F Harvey

INDIAN RESEARCH FUND ASSOCIATION REP SCIENT ADVISORY BOARD FOR YEAR 1ST JAN TO 31ST DEC 1943 1-7 Cholera Treatment Enquiry under the Director, School of Tropical Medicine, Calcutta.

The efficacy of sulphanilylguanidine in treatment and the preparation of pyrogen free saline solution for injection are the two main subjects of enquiry Every care seems to have been taken in appraising the value of the drug by the use of controls although it is not stated definitely that they were strictly alternate During the year sulphanilylguanidine was administered in 174 cases in the following doses 5 gm on admission, and 2.3 gm every 4 hours after to make a total of 20 gm in 24 hours. A control series also of 174 cases is presented and this series by the criterion of proportion of patients with suppression of urine was identical in number and character with the test series Mortality was only 1.72 per cent in the treated cases and 6.32 per cent in the control series a percentage which is markedly in favour of treatment by sulphanilylguanidine (sulphaguanidine)

Avoidance of accidental temperature and other reactions in the intravenous injection of saline solution is very important and a careful series of clinical

trials and animal experiments with detailed record is presented, to furnish a satisfactory conclusion. As it was difficult to obtain freshly distilled water in quantity measures were taken to make tap water pyrogen-free and suitable for injection. The method adopted was to acidulate 2,000 cc. of tap water with 0.4 cc. of 0.4 per cent potassium permanganate and boil for 2 hours. If the permanganate tinge disappeared, more permanganate was added so as to maintain a trace of colour. At this stage the fluid can be stored, for no organism could grow in the acid water and produce pyrogen. At the time of use as saline solution this water was filtered through filter paper and 5-10 drops of hydrogen peroxide were added to it. Slight heating removed excess hydrogen peroxide and, when cool, the pH was adjusted to 7.1 with caustic soda solution. It may be concluded from the detailed experiments that "pyrogen free water can be prepared by treating water with acid potassium permanganate as by the process of distillation. Other experiments were directed to the determination of optimum pH (7.1) and the effect of oxidizable matter on reaction following injection. The following conclusion is reached—"The reactions following intravenous injections of saline solutions are due to pyrogen (a bacterial product) an oxidizable matter and higher or lower hydrogen ion concentration of the solution."

W F Harvey

INDIAN RESEARCH FUND ASSOCIATION. REP. SCIENT. ADVISORY BOARD FOR YEAR 1ST JAN TO 31ST DEC. 1944 1-4. Cholera Treatment Enquiry under the Director School of Tropical Medicine, Calcutta.

Sulphaguanidine has already been tested and proved successful in the treatment of cholera, but as the trials were in patients seriously collapsed, transfusion of saline solution had to be used also and was a statistical complication. An opportunity has arisen in an epidemic of 97 cases to use sulphaguanidine early and to dispense with the saline solution. There were 53 cases thus treated, leaving 44 cases as controls. The results are recorded under the headings, recovered, died, unknown for sulphaguanidine 79.17 and 4 per cent respectively for the control series 25.73 and 0 per cent. Vibriocidal and vibriostatic tests of sulphaguanidine with culture media showed that it had both properties, but that the bactericidal effect *in vitro* was poor.

Tests of another sulphonamide drug, sulphasuxidine (succinyl sulphathiazole) on serious cases requiring intravenous saline therapy with alternate case control were entirely disappointing.

W F Harvey

GUPTA, S. K., CHATTERJEE, B. C., PAUL, B. M. & GHOSE, R. N. Sulphanilylguanidine in Cholera. *Indian Med Gaz.* 1945 June v 80 No 6 288-90.

Preliminary trial had shown the harmlessness of sulphanilylguanidine (sulphaguanidine) and it was accordingly decided to try larger doses than previously. A large series of cases (525) of cholera was available and 263 were treated with sulphaguanidine, the rest being alternate case controls. Saline transfusions were given in both groups as required. The dosage in these cases was 5 gm sulphaguanidine on admission and 2.5 gm. every 4 hours to reach a total of 20 gm. in 24 hours. Beneficial effect was quickly seen and, of 86 admitted with suppression of urine 72 passed urine within 24 hours. This result is contrasted with that in the 72 patients of the control group who also had suppression, of whom only 23 passed urine in 24 hours. Deaths among the 263 sulphaguanidine cases were only 3 whereas 13 out of the 262 controls died. A note is made of seven patients in the control group not expected to recover and developing pre-uræmic symptoms, who did recover when given sulphaguanidine as a last resort. No case treated with sulphaguanidine

developed uraemia. Experiments were conducted also to show that sulphaguanidine had some vibriocidal and vibriostatic action *in vitro*

W F Harvey

INDIAN RESEARCH FUND ASSOCIATION REP SCIENT ADVISORY BOARD FOR YEAR 1ST JAN TO 31ST DEC. 1943 9-21 Enquiry on the Statistical Evaluation of Anti-Cholera Inoculation in the Madras Presidency under the Director, King Institute, Guindy, Madras, and the Director of Public Health, Madras.

Up to the present day there have been very few sound statistical attempts to evaluate the effect of any prophylactic vaccine nor does the present careful attempt for cholera conform to the requirement of the alternate case or the alternate village. It is however genuinely statistical and not impressionist. A very full account is given of the conditions under which the trial was made. According to RUSSELL [this *Bulletin* 1925 v 22, 765 1926 v 23 191 1927 v 24 47] whose statistical study is one of the best the epidemiology of cholera in Madras Presidency is closely related to monsoons and there is a seven yearly [six yearly ?] periodicity when there is a marked exacerbation in the incidence of the disease. In Madras the last periodic wave with 70 000 deaths was in 1935-36 and it seems that the present wave began in the first quarter of 1942. Specially devised cards were printed for the present investigation which applied to 2,300 villages of South Arcot. A total of 2,670 cards was obtained relating to 1 283 villages in the district. The reality of immunization against cholera was the main fact studied. Certain special definitions are laid down to give precision to the results. The population of the 1,283 villages was 1,334 016 of whom 392,115 were protected by means of a single dose of Inaba-Ogawa vaccine. An incidence rate per mille of 1.5 for the protected and 17.1 for the unprotected was found which for a 4-fold table gives χ^2 as 5478.7 and P less than 0.0016. The difference in incidence rates as proof of immunity is undoubtedly significant. Another important point which received attention was that of the time required to establish immunity by vaccination. For cholera a period of six days is prescribed in the International Quarantine Regulations. In the present epidemic it was found that on each of the three days following the date of inoculation the rate of incidence of cholera among the inoculated shows little variation. This rate shows a progressive decline from the fourth day onwards and the minimum is reached on the 10th day after inoculation. The conclusion is arrived at that uninoculated persons in a population at risk are susceptible to an extent of over 10 times in getting cholera as compared with the inoculated persons. When investigation is made of the benefit of vaccination to the inoculated person if he does contract cholera it is found to be negligible. This field study is continuing.

W F Harvey

INDIAN RESEARCH FUND ASSOCIATION REP SCIENT ADVISORY BOARD FOR YEAR 1ST JAN TO 31ST DEC. 1944 4-21 Enquiry on the Statistical Evaluation of Anti-Cholera Inoculation in the Madras Presidency under the Director, King Institute, Guindy, Madras, and the Director of Public Health, Madras.

This enquiry follows very closely in method and in text that dealt with in the report of the previous year. It has of course larger figures to deal with although the main findings are much the same. The protected persons are now 709,977 and the unprotected 2,119,568 with an incidence of cholera of 1.57 and 16.20 per 1 000 respectively. In this case the χ^2 value is 9135.09.

and P is less than 0.0016. In all, 2,350 villages were infected and 627 of these experienced more than one outbreak. The data obtained in the case of villages attacked more than once are used, for analysis of the effects of what are called anticipatory inoculations because the inoculation given in the first outbreak is considered, reasonably, capable of furnishing an answer to the question how far previous inoculation confers immunity. Again a significant difference is observed. The incidence rate in the uninoculated persons was 14.2 times the rate in the anticipatory inoculations. A consideration of anticipatory inoculation leads on naturally to that of the duration of immunity conferred by anti-cholera inoculation. One method of arriving at a conclusion was to observe the relative incidence of cholera in the uninoculated and the inoculated groups in a community in the course of an epidemic lasting for a sufficiently long time and noting the interval between the occurrence of cholera in the inoculated and the dates of inoculation. As it is difficult to find an epidemic lasting long enough to allow of this analysis a better method is to study communities of inoculated and uninoculated persons where more than one outbreak has occurred in the community. A table gives the figures which, though small for statistical purposes "point to the presence of immunity in the inoculated population definitely up to ten months and probably also up to twelve months after inoculation."

BACILLARY DYSENTERY

SCADDING J. G. Sulphonamides in Bacillary Dysentery. Further Observations on their Effects. *Lancet*. 1945 Nov 3 549-53 (29 refs.)

Previously published observations [this *Bulletin* 1944 v. 41 755] suggested that patients suffering from bacillary dysentery showed no significant differences in the duration of their diarrhoea or their length of stay in hospital whether treated with sulphanilamide, sulphapyridine or sulphaguanidine. The present paper records further observations on the sulphonamide treatment of bacillary dysentery. Because sulphaguanidine is the standard drug for the treatment of this disease in the Middle East first succinylsulphathiazole and then sulphadiazine were tested against sulphaguanidine. Secondly observations without controls were made on the effect of smaller doses of sulphadiazine and finally a comparison was made of sulphaguanidine-treated and untreated control cases.

The disease was mild, and in cases where organisms were isolated, 75 per cent. were Flexner infections. The criteria of severity were the duration of diarrhoea before admission to hospital, the number of stools in the 24 hours before admission, and the incidence of fever. The results of treatment were judged by the duration of fever after admission, the duration of diarrhoea, and the total number of days spent in hospital. Treatment, besides sulphonamides, consisted of rest in bed, ample liquid intake, and a bland diet. No toxic complications of sulphonamide treatment developed throughout the investigation. Sulphaguanidine was given in a dosage of 7.0 gm. followed by 3.5 gm. four-hourly reduced after 48 hours if the patient's condition had improved, the average total amount given being about 70 to 80 gm.

Succinyl-sulphathiazole less well absorbed than sulphaguanidine was given in a dosage of 2 gm. five times daily for 3 days then four times daily for 4 days, the course being cut short if there was early improvement. With this course the durations of fever and diarrhoea were very similar to those of the patients treated with sulphaguanidine. The only differences were that the

sulphaguanidine-treated patients were in hospital on the average, 13 days longer than those treated with succinyl-sulphathiazole and showed a greater tendency to recurrence of diarrhoea during convalescence

In the comparison of sulphadiazine with sulphaguanidine the former drug being readily absorbed was used in dosage of 1.0 gm five times daily reduced after 48 hours if there was improvement to thrice daily. The cases in the two groups were comparable in severity. Those treated with sulphadiazine had on the average slightly shorter fever and very slightly shorter duration of diarrhoea and of stay in hospital than those treated with sulphaguanidine. With reduced doses of sulphadiazine down to 3 gm daily the results were little different the duration of fever and of diarrhoea was very slightly longer but the stay in hospital was rather shorter than in the series treated with larger doses.

In the series of control cases treated by rest and diet only the mean duration of diarrhoea was 5.0 days and of stay in hospital 12.3 days. The corresponding figures for alternate cases treated with sulphaguanidine were 4.4 and 10.8 days. The differences between treated and untreated groups were not statistically significant but it is possible that in the figures for all cases a beneficial effect on a few severe infections was being masked by dilution with a large number of mild self terminating ones and in six Shiga cases there was suggestive evidence that sulphonamide treatment had proved beneficial.

The author gained the impression that sulphadiazine cut short long-continued bacillary-type dysentery on which the poorly absorbed sulphonamides had had no effect. He suggests that in these chronic cases the action of sulphonamides is to combat invasion of the bowel wall by secondary invaders by virtue of their concentration in the blood rather than on the dysentery bacilli by their concentration in the lumen of the bowel where there are likely to be inhibitory substances. On this hypothesis action in acute cases is simply prophylactic against ulceration, either by the dysentery organisms or by the secondary invaders. This would explain the difficulty of detecting any differential effects in mild cases the irregular response in severe cases since the response will depend on what secondary invaders are prominent and finally the fact that small doses of readily absorbable sulphonamides which for other infections would be regarded as prophylactic rather than therapeutic gave as good results in acute bacillary dysentery as larger doses of the poorly absorbable compounds.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

DRUCKMANN A & SCHORR S The Roentgenological Manifestations of Amebiasis of the Large Intestine *Amer J Roentgenol & Radium Therapy* 1945 Aug v 54 No 2 145-8 7 figs

Where there is stenosis of the large bowel the radiologist should consider the differentiation of cancer and amoebiasis. Amoebiasis of the colon is either (1) diffuse or (2) localized. In the diffuse type the lesions scattered throughout the colon radiographically resemble those seen in idiopathic ulcerative colitis. In the localized type a more characteristic X ray appearance is seen in order of frequency in the caecum ascending colon sigmoid and rectum. An opaque enema gives a more reliable picture than a barium meal.

The differentiation of a localized amoebic lesion of the large bowel from a cancer can be made on a number of grounds.—The amoebic lesion occupies an extensive segment of the gut the lesions in amoebiasis are frequently multiple while the constriction of the bowel is relatively incomplete and is

intra-abdominal pressure as well as from infectious hepatitis and other forms of hepatomegaly. Some types of pulmonary disease bronchostenosis for example, may give rise to paradoxical movement of the diaphragm. Also in amoebic hepatitis the diaphragm may show no change if the upper portion of the liver is not remarkably involved. In the present group abnormal radiological signs were present in only 15 (45.4 per cent.)

In only two was the complement fixation test of Craig carried out—one was positive the other anticomplementary. There were difficulties in the way of carrying this test out as the material had to be sent away and a long time elapsed before results became available.

COUTTS, W. E. Urethritis por enteroparasitos. (Entamoeba histolytica y Lamblia intestinalis) [Entamoeba histolytica and Giardia intestinalis in Urethritis.] *Rev. Chilena de Hig. y Med. Preventiva* 1945 Mar. v. 7 No. 1 3-5 English summary (9 lines)

The author relates that in an earlier publication he has called attention to the frequency with which trichomonas and spirochaetes can be detected in urethral discharges. In the present paper he describes two cases of urethritis in the discharge of one of which *Giardia intestinalis* was discovered and in that of the other *Entamoeba histolytica*. In both cases a cure was obtained by injections of pergonon

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

DEWAR, H. A. & WALMSLEY R. Relapsing Fever with Nephritis and Sub-arachnoid Haemorrhage. *Lancet* 1945 Nov 17 630-31

The description of a fatal case of (presumably) tick-borne relapsing fever in a soldier convalescent from amoebic dysentery. The patient had spent most of the previous four months in the western desert of Egypt.

The attack developed whilst he was still in hospital after his stools had become negative for *Entamoeba histolytica* and treatment with carbarsone tablets (0.25 gm. twice daily by mouth) had begun. On the 5th day *Spirochaeta recurrentis* was found in large numbers in a blood film. On the 7th and 8th days the blood was negative, but the patient was severely ill and his blood urea rose to 300 mgm. per 100 cc. on the 10th day.

After only one bout of fever nephritis and severe epistaxis supervened and the patient died on the 12th day as the result of a subarachnoid haemorrhage.

Autopsy was performed 2½ hours after death and attempts were made without success, to detect the presence of spirochaetes in the bone-marrow, brain and spleen both by examining smears and inoculation into mice. Microscopically as well as *in vivo* the most striking feature of the nephritis

was its intensely haemorrhagic character which together with the epistaxis and the perirenal and subarachnoidal haemorrhages suggests a general haemorrhagic tendency in this case. *E Hindle*

[No information as to the species of tick responsible for transmission is given and the evidence is presumptive only similarly it is assumed that the organism was *S recurrentis* but no detailed investigation was possible.—*Ed*]

LAHIRI M N *Leptospirosis without Jaundice. Indian Med Gaz* 1945 July \ 80 No 7 338-7

The author describes the clinical symptoms of a patient admitted to hospital for fever headache and agonizing pains all over the body He was seen on the eighth day of illness. The urine showed total absence of bile salts and pigments but a trace of albumin was present Cultures and animal inoculation of the patient's blood were negative but the serum reacted to a titre of 1:1,280 with a local strain of leptospira

A total of 225 samples of sera sent in to the Haffkine Institute Bombay for Widal tests were examined for leptospira by serological tests against three strains One serum showed a titre of 1:640 and as it had been sent for Widal test jaundice was presumed to have been absent *E Hindle*

MOHANTY J K *The Occurrence of Leptospirosis in Orissa. Indian Med Gaz.* 1945 July \ 80 No 7 337-8 [11 refs.]

The record of a patient admitted to hospital for the treatment of haematemesis melaena and jaundice The agglutination reaction against a classical strain of *Leptospira icterohaemorrhagiae* was negative Nevertheless the urine when centrifuged showed the presence of spirochaetes closely resembling leptospirae. Animal inoculations were not possible *E Hindle*

LAHIRI M N *The Unsuitability of White Mice for Studies of Leptospirosis. Indian Med Gaz* 1945 July \ 80 No 7 338-9

Three-weeks-old Haffkine Institute inbred mice and also Javanese mice were inoculated with varying doses of two virulent cultures of *Leptospira icterohaemorrhagiae* in batches of three

In the first series out of 36 mice all survived except one and in the second series of 30 Javanese mice there were only two deaths from the infection In addition six Swiss mice were tested and all survived. The control guinea pigs all succumbed between the fifth and seventh day after inoculation.

These experiments therefore do not support LARSON'S results (see *Bulletin of Hygiene* 1942 v 17 144) at least so far as laboratory studies of leptospirosis in India are concerned. *E Hindle*

HELMINTHIASIS

MAZZOTTI L. *Presencia de huevecillos de varios helmintos diferentes del E vermicularis en la region perianal de individuos examinados en Mexico para investigar oxuriasis. [The Presence of Ova of other Helminths in the Perianal Region of People in Mexico examined for Oxyuriasis.] Rev Inst Salubridad y Enfermedades Trop Mexico* 1945 June \ 6 No 2 131-5 English summary (4 lines)

The examinations were made in four seaside localities with a tropical climate and in Mexico City which has a temperate climate 1,260 schoolchildren were

examined in the former places and 1,229 children and 500 adults in Mexico City. GRAHAM's method with Scotch cellulose tape [this *Bulletin* 1942 v 39 790 1943 v 40 617] was used.

The results are given in detail in a table. Among the 2,989 persons examined helminth ova other than those of *Enterobius vermicularis* were found in 188 (6.6 per cent.) they included ova of *Ascaris lumbricoides* (96) *Trichuris trichiura* (100) hookworm (6) *Taenia* (26) and *Hymenolepis nana* (3).

The children in the tropical localities had a greater incidence (up to 20 per cent.) than the persons in Mexico City (2.8 per cent.) The author discusses the point whether the proglottides of *Taenia solium* migrate through the anus.

J. F. CORSON.

McMULLEN D. B. & BEAVER, P. C. Studies on Schistosome Dermatitis. IX. The Life Cycles of Three Dermatitis-producing Schistosomes from Birds and a Discussion of the Subfamily Bilharziellinae (Trematoda: Schistosomatidae). *Amer J Hyg* 1945 Sept., v 42, No 2, 128-54 1 fig & 3 pls. [35 refs.]

"1. Techniques used in detecting schistosome infections in birds are described.

"2. In experiments with three dermatitis-producing schistosome cercariae *C. physellae* Talbot, *C. clae* Miller and *C. stagnicolae* Talbot adult schistosomes have been recovered from birds. After examining these trematodes and the literature on members of the subfamily Bilharziellinae Price 1929 the adults of *C. physellae* Talbot were determined as *Trichobilharzia physellae* (Talbot) (syn. *Pseudobilharzia quercupulac* McLeod) n. comb. the adults of *C. clae* Miller as *Trichobilharzia ocellata* (La Valette) (syn. *T. kousarcus* Skrjabin and Zakharov) and the adults of *C. stagnicolae* Talbot as *T. stagnicolae* (Talbot) n. comb.

"3. A revision of the generic diagnosis of *Trichobilharzia* is proposed. This reduces the genus *Pseudobilharzia* Ejsmont to synonymy with *Trichobilharzia*. Since it is difficult to differentiate species in this genus on the basis of adult morphology it is concluded that the eggs may be one of the most reliable characters for this purpose.

"4. While no attempt has yet been made to find these three common species in resident or migratory birds in the vicinity of infested beaches it is evident from earlier studies that the most common natural hosts are migratory birds, and the present study has shown that *Trichobilharzia ocellata* and *T. physellae* develop in ducks and other birds while *T. stagnicolae* was found to reach maturity in canaries only.

5. In all three species eggs are produced in about 2 weeks after infection and there is some evidence that the infection does not last longer than 1 or 2 months.

6. Protecting beaches from flocks of migrating birds especially in the fall may be of value in preventing schistosome dermatitis on bathing beaches.

HARRIS, J. R. & HICKEY, M. D. Occurrence of the Diphylobothriidae in Ireland. [Correspondence.] *Nature* 1945 Oct. 13 447-8.

This paper further discusses the occurrence of plerocercoids of Diphylobothriidae found by the authors [this *Bulletin* 1944 v 41 858] in trout in Poulaphuca reservoir near Dublin by DUGGID and SHEPARD [*ibid* p. 857] in trout in a South Wales reservoir and by GIBSON [*ibid* 1945 v 42, 396 see also LYNWORTH, *ibid* p. 397]. BAYLIS [*ibid* p. 806] has examined adult Diphylobothriids reared experimentally in dogs from the Dublin and South Wales

plerocercoids and considers that all these plerocercoids and also the adults obtained from gulls and cormorants by the authors mentioned above probably belong to the Diphyllbothrid species *D dendriticum* (Nitzsch) which is normally parasitic in gulls although those found in the cormorants may be *D ditremum*. The possible confusion of the plerocercoids of these bird species with those of *D latum* of man required further investigation because it is very difficult to distinguish from one another the plerocercoids of different species of Diphyllbothridae. The difficulty is increased in Ire because *D latum* does occur there. Harris and Hickey here record references to its occurrence the first record being that of BELLINGHAM—and O BRYAN—(*Ann Mag Nat Hist* 1844 v 14 251). To these records Harris and Hickey add another recent one. They received from Dr T V McLoughlin a specimen of *D latum* recovered from a boy aged 14 who had eaten perch from Gardice Lake Co Leitrim. Harris and Hickey searched 79 perch from this lake for plerocercoids and found from 1 to 8 plerocercoids per fish in 35 of the 79 perch examined. Similar plerocercoids were found in two perch from Lough Allen Co Leitrim. Plerocercoids from the Gardice Lake perch were given by mouth to two adult dogs and from both of these dogs which were given 2 and 8 plerocercoids respectively adult Diphyllbothrids were recovered. The two adults obtained from the dog given 2 plerocercoids were specimens of *D latum*.

Harris and Hickey compare the plerocercoids obtained from trout of Poulaphuca reservoir Dublin (namely those of *D dendriticum* of gulls or *D ditremum* of cormorants) with those from the perch from Gardice Lake from which they experimentally reared *D latum*. They note the following differences—

The plerocercoids of *D latum* were opaque and dull white and were only sluggishly motile. They seldom relaxed sufficiently to lose their typical irregular deeply wrinkled appearance. When they were killed in tap water the scolices usually remained invaginated and showed deep wrinkles. Of the 81 plerocercoids found in the perch of Gardice Lake 71 were found in the skeletal muscles and only 10 in the peritoneal cavity or abdominal viscera. There was no inflammatory reaction around them.

The plerocercoids of the trout from Poulaphuca reservoir (of the bird species) were translucent glistening white and actively motile. They showed no wrinkling except when they were strongly contracted. When they were killed in tap water they invariably relaxed and evaginated and wrinkles were never present although some showed segmentation. Out of the 198 infested trout examined only one had plerocercoids in the skeletal muscles (two were found in it) in all the others the plerocercoids were in the viscera or subserous tissues of the abdominal cavity. Around them there was often an inflammatory mass of blood stained granulation tissue.

The authors examined fish from other Irish waters namely reservoirs in Wicklow and Dublin Counties Lough Mask Co Mayo four Lakes in Connemara, Co Galway and Lough Eske Co Donegal. Plerocercoids superficially resembling those found in trout from Poulaphuca reservoir (i.e. presumably plerocercoids of Diphyllbothridae parasitic in birds and not in man) were found in trout (*Salmo trutta*) salmon (*S salar*) and char (*Salvelinus colii*) G. Lapage

GRASA A. Alergia y diagnóstico biológico de la hidatidosis. [Allergy and the Biological Diagnosis of Hydatid Disease.] *Arch Uruguayos de Med Cirug y Especialidades* 1945 June v 28 No 6 538-59 [75 refs.] English summary

It is not possible to abstract in detail this review of an extensive bibliography of this subject. The author considers much South American work which is not readily accessible and also incorporates his own experience. Many

of the papers considered are also reviewed by TALIAFERRO (*The Immunology of Parasitic Infections* 1929 Century Co. London and New York)

In the course of his discussion of the technique and significance of the immediate and delayed (Casoni) intradermal reaction, GRAZIA reminds us that tuberculosis is among the conditions other than hydatid disease which may give rise to falsely positive intradermal reactions to the injection of hydatid fluid. He quotes the work of DABOWSKY (cited by MOLLON see this *Bulletin* 1931 v 28 205) who obtained a high percentage of positive intradermal reactions with hydatid fluid in tuberculous children [cf DAVIS HARRELL and KING *Bulletin of Hygiene* 1946 v 20 673]. GRAZIA states that statistics show that positive Casoni reactions are most numerous in subjects with hydatid cysts of the liver and next most numerous in those with cysts of the lung. In his experience strongly positive Casoni reactions may occur even when hydatids of the liver and lung are suppurating or are calcified but they are often negative in subjects with cysts in the bones or brain.

The technique and significance of the Prausnitz Kustner test applied to hydatid disease is discussed. GRAZIA obtained a positive Prausnitz Kustner reaction in only one of many subjects who gave a strongly positive Casoni intradermal reaction but he considers, nevertheless that the passive transference of hypersensitivity is possible.

Human hydatid fluid has, he considers, a very low antigenic power. The sterile cysts of the liver and lung of sheep give the best hydatid fluid for use as antigen. FERNANDEZ ITHURRAT and CALCAGNO [see this *Bulletin* 1924 v 21 208] obtained, however, just as good results with human hydatid fluid as with fluid obtained from oxen and sheep. They maintain that the antigenic power of the fluid should be tested both on healthy subjects and on subjects with hydatid cysts before it is used. Discussing the nature of the substance which provokes the intradermal reaction GRAZIA recommends for use either 0.1 cc. of hydatid fluid previously tested, or the protein fraction obtained by DEXNIS (*J. Parasitology* 1937 v 23 60) who isolated a protein by precipitation with 5 per cent. trichloroacetic acid and obtained with it intensely positive reactions with erythema prolonged for 48 hours and oedema lasting 4 to 5 days. [See also the polysaccharide and protein obtained and tested by PIROSKY *et al* (this *Bulletin* 1943 v 40 474).]

The author next discusses the blood eosinophilia and the local eosinophilia which may both result from the injection of small amounts of hydatid fluid into subjects with hydatid cysts. In hydatid disease the blood eosinophilia is not significant unless it exceeds 5 per cent. but values higher than 5 per cent may occur when infestations of the muscles and blood with other parasites are present and also when there are skin affections, allergic conditions etc. [cf DIXON and HARGREAVES (this *Bulletin* 1945 v 42, 907) who discuss the results of their study of 284 cases of cysticercosis due to *Taenia solium* and quote the opinion of GOTOR (this *Bulletin* 1943 v 40 65) that Continental workers have attached too much importance to blood eosinophilia, which Dixon and Hargreaves found in only 10 per cent. of their cases. They agree with MACARTHUR (this *Bulletin* 1934 v 31 384) that such deviations from the normal eosinophilia of the cerebrospinal fluid as may occur have no diagnostic significance and that the cerebrospinal fluid generally remains unaffected even when there is gross cerebral cysticercosis. GRAZIA, on the other hand, refers in the paper here reviewed, to the view of PARVU and LAURKY (*C.R. Soc. Biol.*, 1909 v 68 467) that "the eosinophilia of the cerebrospinal fluid which is so characteristic of cerebral cysticercosis (see GRAZIA & SCHWONE this *Bulletin* 1942, v 39 705 and SELMAN *ibid* 1945 v 42, 816) is not present in hydatid disease. GRAZIA insists that both the relative and the absolute eosinophilia of the blood must be considered. He found that the subcutaneous or

intradermal injection of even as much as 10 cc. of hydatid fluid did not cause in healthy subjects a significant increase of eosinophils in the blood but in subjects with hydatid disease repeated injections of hydatid fluid caused eosinophilia in proportion to their sensitivity as indicated by the degree of the Casoni reaction. One subject tested by Graña showed a local eosinophilia so intense that the fluid in the local blister contained 29 per cent of eosinophils. Although MOLLOW (*loc cit*) does not attribute diagnostic value to this induced eosinophilia Graña considers that it has real diagnostic value if it is considered in relation to the other blood changes provoked.

The author next reviews some of the literature on the complement fixation (Ghedini Weinberg) reaction. Like the Casoni reaction it may give false positives in subjects suffering from haemangioma or primary cancer of the liver (see MOLLOW *loc cit*). PARVU and LAUBRY (*loc cit*) record that in subjects with cerebral hydatids the complement fixation reaction done with cerebrospinal fluid is positive although it is negative when it is done with blood.

Discussing heterophil antibodies Graña refers to the work of CALCAGNO (*Boletines y Trabajos de la Acad Argent de Cirurg* 1939) who studied the effects of the injection of hydatid fluid into subjects harbouring hydatid cysts and called this procedure the biological therapy of hydatid disease [*cf* RIVAS GÓBICH and MANTILLA this *Bulletin* 1945 v 42, 910]. Graña (*Dia Méd* Buenos Aires, 1943 v 14 1092) (see also this *Bulletin* 1944 v 41 764) has observed in the serum of subjects thus treated a notable increase of haemolysins and agglutinins for the erythrocytes of sheep and has obtained agglutination in dilutions of serum as high as 1:2048 and haemolysis in dilutions of 1:4096 using the technique of PAUL and BUNNELL (*Amer J Med Sci* 1932 v 183 90) for the diagnosis of infectious mononucleosis. Graña noted great variability in the titres of heterophil antibodies shown by different individuals harbouring hydatid cysts in relation to the same antigen. He has found [this *Bulletin* 1944 v 41 764] that in rabbits and in subjects without cysts injection of hydatid fluid does not cause an increase of agglutinins and haemolysins to erythrocytes of sheep while in subjects with cysts the rise in these heterophil antibodies is strictly parallel to the degree of hydatid allergy shown by the Casoni intradermal reaction done upon them. Graña (*Arch de Med Cirug y Especialidades* 1944 v 24 471 and *Clinica e Immunologia* Edit. Espasa Calpe 1944) found that the formation of these heterophil antibodies is rapid and intense and that this serological reaction has a certain diagnostic value (see also Graña *Medicina* Buenos Aires 1945 *in the press*). Graña has also seen a notable increase of agglutinins and haemolysins to sheep erythrocytes in the sera of sensitive subjects into whom extracts of *Ascaris lumbricoides* of the pig have been injected (*Rev Brasileira Biol.* 1945 v 5 81). The author then describes what he calls the triple response to the introduction of antigen. If the eosinophilia exceeds 5 per cent and the intradermal and complement fixation reactions are positive one can be sure that the subject has a hydatid cyst. If all or some of these reactions including titration of the serum against the erythrocytes of sheep are negative and if we wish to increase the efficacy of the reactions the triple response can be tried. Hydatid fluid (2 cc.) is injected intradermally into separate sites in the skin each day for five days if after 96 hours or with more certainty after 48 hours from the beginning of the reaction a negative complement fixation reaction has become positive and the eosinophils have exceeded 5 per cent it is necessary to suspect hydatid disease because subjects without cysts do not react in this way in so short a time (see Graña *Arch. de Med Cirug y Especialidades* 1944 v 24 471 and *Medicina* Buenos Aires 1944 v 4 290). Five to ten days after the last injection the late response shown by increase of agglutination

of sheep erythrocytes is studied, and if the titre of this is above 1:32 by the technique of Paul and Bunnell there is further reason for the diagnosis of hydatid disease.

The author next discusses histaminaemia in hydatid allergy. Graña *et al.* (*Medicina*, Buenos Aires, 1943 v 3: 98) found that histaminaemia in subjects with hydatid disease is very variable. High values were found in subjects with hepatic hydatid, three of whom had calcified cysts. One subject with a small calcified hydatid had marked digestive troubles and his histaminaemia rose to the titre of 48 gammas per cent. Such high values suggest a relation to the increased number of eosinophils in the blood, for CODE (*J. Physiology* 1937 v 89: 257) suggested that the eosinophils carry the histamine. RANDOLPH and RACKEMANN (*J. Allergy* 1941 v 12: 450) could not, however, accept this view, and Graña and his collaborators found no relation between the absolute or relative number of eosinophils and the degree of histaminaemia, nor did he find histamine in the vesicle produced by injection of hydatid fluid, although in this there were 29 per cent. of eosinophils.

Clinically subjects with hydatid disease can show various signs of classical allergy such as asthma, urticaria, angioneurotic oedema and other symptoms which rapidly yield to desensitization with hydatid fluid. The author refers to instances of asthma which were clearly of hydatid origin and to the provocation of a severe asthmatic state by the injection into a subject with a hydatid cyst of the lung of excessive quantities of hydatid fluid. JAUREGUY and SOTO (*Alergia hidatidea pulmonar* Monografía Imprenta Rosgal, Montevideo 1941) interpret radiological shadows in the lung near a hydatid as of hydatid origin. There are many instances of chronic and stubborn urticaria which have vanished when the hydatid cyst has been removed. In one subject cited by Graña it disappeared after the first desensitizing injection of hydatid fluid. Various other symptoms may also disappear after similar injections. Among the most notable results of this biological therapy (see Calcagno above) is the rapid disappearance of dyspeptic pains and symptoms of a hepatic or biliary type in subjects with calcified liver hydatids and without any lesion of the gall bladder (*cf.* Graña, *Bol. de la Soc. de Ciruj. de Montevideo* 1943 May and *Dis. Véd.* Buenos Aires, 1943 v 14: 1092, and *Prensa Med. Argentina* 1944 v 31 No 16).

Discussing anaphylactic shock due to the rupture accidental or during surgical operations, of hydatid cysts and the consequent rapid and massive absorption of antigen by subjects previously sensitized, the author quotes the view of CHAUFFARD *et al.* (*C.R. Soc. Biol.* 1909 v 67: 499) that this sensitization is slow and chronic, being produced by the passage of hydatid fluid through the wall of the intact cyst or through small fissures in the cyst. Death may result from this shock. DUBOIS (*Rev. de Chir.* 1911 v 1: 153) describes post-operative hydatid intoxication which corresponds to anaphylaxis due to reabsorption of hydatid fluid: this kind of phenomenon does not occur during operation, because the general anaesthesia inhibits the signs of shock, which may be benign or severe. Graña suggests that the study of experimental shock shows that hydatid fluid is a primary toxin to cells, and it is possible that what is interpreted, in man, as pure anaphylaxis may be a combined result of anaphylactic phenomena and primary toxicity of hydatid fluid.

The author then discusses experimental hydatid anaphylaxis and reviews literature on this question which shows, he thinks, that there has been difficulty in producing experimental anaphylaxis. LEVMAIRE thinks that this difficulty may be due to the fact that hydatid fluid is poor in proteins. DESAY and MAROTTA (*Rev. de la Soc. Méd.* 1912, v 20 p. 373) produced shock in dogs by the intravenous injection of 20 cc. of hydatid fluid, and GIVERT and HEG (*II Congreso de Medicina* Buenos Aires, 1922, v 1: 691) confirmed this and also

produced shock by injection of hydatid fluid which had been either boiled or ultrafiltered. They found that the histamine titres were so small that the effect of this substance could be ignored. Graña has confirmed the results of Giusti and Hug. Graña and his colleagues (*Rev de la Soc Argent de Biol* 1943 v 19 444 and *Amer J Physiol* 1945 v 143 306) showed that in some dogs the histamine increased in the blood during the shock while in others the histaminaemia increased so that histamine could not have been the cause of the shock. A substance can however be extracted from hydatid cysts which is responsible for the shock this is not a protein it is resistant to heat and is precipitated by acetone. A dose of 60 mgm. produces in dogs a profound shock which is followed by desensitization. *G Lapage*

DEFICIENCY DISEASES

TROWELL H C & MUWAZI E M K Severe and Prolonged Underfeeding in African Children. (The Kwashiorkor Syndrome of Malignant Malnutrition) *Arch Dis in Childhood* 1945 Sept v 20 No 103 110-16 5 figs [30 refs]

The name kwashiorkor is a tribal word from the region of Accra in the Gold Coast and is not understood outside this area, but the syndrome for which it stands is found in many parts of Africa and possibly elsewhere. This syndrome includes a pale red skin with brownish hair a crazy pavement dermatosis wasting oedema anaemia lowered plasma albumin and raised globulin a gastro-intestinal defect seen radiographically as gross segmentation of the small gut and marked fatty degeneration of the liver. In its advanced stages the syndrome is notably refractory to treatment. The syndrome has frequently been taken to be a manifestation of pellagra but this view is no longer tenable. The anaemia at least in Uganda is macrocytic and hypochromic megaloblasts are seldom if ever seen in films of peripheral blood or bone marrow.

Adding to the previous descriptions of the senior author Trowell and Muwazi during 1945 examined 180 children 126 of them out patients and 54 in patients at Kampala Uganda. After the sixth month about three-quarters of all cases attending the clinic showed signs of the syndrome. Plasma proteins were determined in 20 patients in most cases the plasma albumin was low and the plasma globulin was high so that the albumin/globulin ratio was low in every case this ratio was below the mean albumin/globulin ratio for normal children in many cases it was less than 1.

Malaria parasites were found in 119 of the 180 children. Among these same children were 17 probable cases of congenital syphilis. Of the 54 cases in the wards of the hospital 12 had pneumonia, 4 bacillary dysentery, 1 amoebic dysentery, 14 ankylostomiasis, 4 ascariasis and 6 giardiasis. Thus in the tropics kwashiorkor is seldom seen uncomplicated by infection of which the most important is malaria. The syndrome has however been observed in South Africa almost uncomplicated by tropical disease.

The authors think that the syndrome may be the same as severe marasmus in European children with a few variations due to the peculiarities of the

African diet. They also point out that it is almost impossible to distinguish the syndrome from coeliac disease, although in "kwashiorkor" oedema is far more common and many more cases proceed rapidly to marasmus and death.

A trial of denoicated hog's stomach in six cases gave encouraging results one case is described in some detail. This child, who had severe oedema, showed no improvement during a fortnight on a high-calorie, high-protein diet plus thiamin and nicotinic acid, nor during a further 4 days with daily injections of liver extract. Denoicated hog's stomach given by mouth was followed by a remarkable and rapid improvement. [See also GILLMAN *et al* this *Bulletin* 1944 v 41 1057 1945 v 42, 748 1946 v 43, 59]

The authors suggest that the syndrome should be called "malignant malnutrition."

QUITTER, F Beiträge zum Pellagraproblem. [Contributions to the Problem of Pellagra.] *Deut Tropenmed Ztschr* 1944 Jan. 1 v 48 Nos. 1/2, 18-25 [11 refs.]

The author is convinced that pellagra in Rumania presents several differences from the disease elsewhere—so much so that he regards the so-called pellagra in some of the Balkan districts as pseudo-pellagra and not true pellagra at all. In Rumania the disease was present where maize was much used, and when other grains took its place pellagra diminished. On the other hand cases are seen in Rumania in which maize plays no part and the disease is seen in the better nourished and well-to-do families. In Rumania the disease is typically seasonal—cases begin to appear at the end of February and the beginning of March, and increase until the summer when they begin to fall in numbers by late autumn and the start of winter they disappear altogether. The symptoms typically are tiredness, apathy and later—often much later—glossitis, burning sensations in the throat, digestive disturbances, erythema of hands, feet, face and neck. There may be no relapse the following year even though the patient remains at home and in no way changes his mode of living. Mental disturbances appear late.

The author does not regard pellagra as purely an avitaminosis, because it is rare to see more than one case in a family (of 79 patients in 1941 only two were members of one family) and cure takes place without increase of vitamin.

There may be a constitutional endocrine factor and some cases wear up quickly when sexual hormones are given. In others there is evidence in favour of some sensitizing factor as photosensitivity—the gastritis may be of a "constitutional" nature, when relapse is likely to occur or it may be accidental and fortuitous and, if so, once cured it is not likely to return. Allergic diseases are commoner in females says the author and 91 per cent of his patients were women, and treatment with specific anti-allergics, as Reticulin or Torantil [both are prepared from animal tissues] yielded good response. The allergy might be endogenous (auto-intoxication) or exogenous, perhaps due to some toxin in spoiled maize.

The author quotes several cases which improved on Reticulin. One a severe case may be cited. A man, aged 20 years, ill each spring for the past two years, worse this year—is apathetic and will not answer questions—has erythema of the face, lips swollen and painful, tongue has many painful fissures, burning sensation in throat and stomach, such that he can take scarcely any food. He was given Reticulin, 2 cc. every other day and improvement started after the fifth injection—the throat and stomach symptoms were eased, the general state was better and three weeks after completion of the course the hands and feet showed only slight pigmentation—he was much more alert and his only complaint was of feeling fatigued sooner than he used to at his work.

The author regards nicotinic acid as having the properties of a vitamin daily administration of 200-300 mgm led to definite improvement in 12-14 days. It is not an anti pellagra vitamin but acts as a constituent of cozymase.

Other patients were treated with Decholin 10 cc injections of 20 per cent strength on alternate days. Here again an example may be quoted a man of 53 years with lassitude erythema glossitis gastritis severe diarrhoea burning pain in the throat. Six injections were given. At the end of the first week his subjective symptoms were vastly improved and by the end of the course he was in general cured. Some redness of the skin remained but that was all.

Neither those treated with Reticulin nor those with Decholin changed in any way their mode of living so that the results may definitely be ascribed to the treatment adopted.

HAEMATOLOGY

DENHOFF E *Hematologic Values of American Soldiers Stationed in the Tropics* *J Lab & Clin Med* 1945 Oct v 30 No 10 874-82.

American medical officers stationed in the South west Pacific had more than once remarked in general terms that each month the red blood cell count seems to be lower and the incidence of eosinophilia increases. The author resolved to put this supposition to the test and examined the blood of 655 American soldiers admitted to hospital and of a small number (33) of healthy soldiers. The former included 142 who had been stationed in the tropics for 6 months the main causes for admission to hospital being bacillary dysentery and acute infective hepatitis. 211 who had been out for 12 months the causes of admission being respiratory diseases bacillary dysentery and malaria and 302 who had been out for 18 months filariasis and malaria were the main diseases in these. In these three groups respectively the average red cell counts and haemoglobin estimations (by the Tallqvist scale) were 4 710 000 per cmm and 88 per cent. 4 560 000 and 88 per cent. and 4 390 000 and 84 per cent. As regards the controls the average of 14 recent arrivals was 4 970 000 and 95 per cent. haemoglobin and of these together with 19 others after a year's stay 4 770 000 and 91 per cent. at the end of two years the average was 4 400 000 and 84 per cent.

Among those in Group I there was only one (0.7 per cent.) noted as a case of borderline normocytic anaemia. In Group II there were 13 (6.7 per cent.) and in Group III 29 (9.6 per cent.). Eosinophilia of 9 per cent. or over was present in 1, 7 and 26 (or 0.7, 3.3 and 10.1 per cent.) respectively in the three groups accounted for by helminthic infestations or dermatoses. For 9 others no explanation was found.

Of 100 patients garrisoning filaria free islands 8 had this degree of eosinophilia, while of 156 on an island where filariasis was endemic 18 (11.5 per cent.) had eosinophilia. Of 140 healthy soldiers on filaria free islands 5 (3.5 per cent.) had eosinophilia compared with 40 (28.1 per cent.) of 142 exposed to filariasis.

It will be seen therefore that the erythrocyte count and the haemoglobin values fell with length of service and it was thought that lack of thiamin, riboflavin and ascorbic acid were contributory factors. Monotony and lack

of palatability of the food were also part causes, the food itself being adequate. The incidence of true anaemia was slight. It is noteworthy that a high incidence of eosinophilia was present in healthy soldiers who had been stationed in a filaria-endemic island, although they presented no clinical evidence of infestation. HOLMES E. G. Observations on Oedema occurring during the Course of Macrocytic Anaemia. *Brit Med J* 1945 Oct. 27 561-4

Oedema and ascites in tropical macrocytic anaemia have usually been attributed to cardiac insufficiency but in the present series of 38 cases of macrocytic anaemia in East African troops in the S.E. Asia Command, oedema and ascites which occurred in 12 did not appear except in one, until as a result of treatment, the blood count had risen considerably and at a time when other signs which could be attributed to cardiac decompensation were entirely absent. As the manufacture of haemoglobin involves the synthesis of protein as well as the production of the iron-containing haem molecule observations were undertaken to ascertain whether any diminution in plasma protein occurred which might explain the oedema and ascites in such cases. Oedema is said to occur if the total protein falls below 5.5 per cent. or the albumin below 2.5 per cent. The osmotic pressure of the serum depends upon the sum of the osmotic pressures of its albumin and globulin components. The albumin is the smaller molecule, and is said to exert about four times as much osmotic pressure as the globulin. The albumin/globulin ratio taken alone has no particular significance it may be low because of increased globulin and a serum in which the albumin is decreased and the globulin normal or raised may therefore exert a lower osmotic pressure than a serum of equal or less total protein content but containing a higher proportion of albumin. From the Tables given in the paper it would seem that oedema in tropical macrocytic anaemia is not explicable solely on a basis of low serum protein.

Although the response to treatment was slow the average duration being 105 days, the majority of patients were ultimately returned to duty. In Category A. Treatment consisted of a daily diet of about 4 000 calories, containing 165 gm. protein of which 38 gm. was derived from meat (muscle) 22 gm. from liver 31 gm. from milk, and 12 gm. from eggs. In addition, each patient received 2 to 4 oz. of a marmite substitute vitamin tablets iron and sometimes 2 oz. of yeast. Some also received liver extract orally or by injection. In only two so treated was a reticulocyte response observed. Two patients showed a reticulocyte response to the marmite substitute. Eight patients had one or more blood transfusions because of their precarious condition, while five of the oedematous patients received intravenous infusions of reconstituted serum. This latter treatment was followed by diuresis and in three cases the oedema and ascites began to clear up a few days later. In the other two it seemed to have little effect. In cases with effusions not causing serious mechanical embarrassment, paracentesis was considered undesirable because it involves loss of protein to the body.

The method used for serum protein determination was based on that of WALTHER (*Lancet* 1941 Sept. 20 337) but in the absence of a colorimeter a Lovibond tintometer with a blood urea disk was used. The serum non protein nitrogen estimations were not entirely satisfactory the colour comparison often being hindered by cloudiness but fortunately the protein equivalent of the N.P.N. is small and the inaccuracy involved not material when the N.P.N. is high the difficulty disappears since greater dilutions can be used. Fractionation of the albumin and globulin was carried out on the usual principles with sodium sulphate. In the absence of suitable filter paper the clear supernatant solution was pipetted off after standing. *F Murgatroyd*

ROSENBAUM S Chronic Leucopenia in Childhood *Harefuah* Jerusalem
1945 Oct 15 v 29 No 8 [In Hebrew 188-91 English summary 191]

Chronic leucopenia (5 500 and fewer leucocytes per cmm) was found in 13 per cent of 880 children. Chronic decided leucopenia (50% and less of the normal leucocyte values for the corresponding age) was found in 3% chronic lymphocytopenia (50% and less of the normal lymphocyte counts for the corresponding age) in 1 7%.

62 5% of these children were underweight.

Chronic leucopenia may be either congenital or acquired. Familial cases were observed.

The condition may continue for years.

In one third of the cases there was an eosinopenia. But considerable eosinophilia may be observed. The eosinophilic system reacts by itself independent of the granulocytic or lymphocytic system.

The percentage of eosinophiles not the total eosinophile count is characteristic of an allergic reaction.

Chronic leucopenia is in the vast majority of the cases a sign accompanying a transient or permanent inferiority of one or more functional systems. These children suffer from catarrhal diathesis, muscular weakness, neuropathic and psychopathic conditions, and allergic affections are also relatively frequent. Nutritional disturbances due to digestive insufficiency and lambliosis may produce chronic leucopenia. In two cases premature birth may have been the cause.

Chronic decided leucopenia and chronic lymphocytopenia correspond in their pathognostic significance entirely to chronic leucopenia. In febrile infections there is an increase in the white blood cells. But this increase is relatively moderate. The children react within the limits of their diminished leucocytic reactive power. In purulent conditions the granulocytes are chiefly increased in catarrhal infections chiefly the lymphocytes.

The sulfonamide drugs and salicylic acid do not seem to be a special danger in the sense of agranulocytosis. Nor have spontaneous agranulocytoses been noted.

WEINGARTEN R J Influence of Temperature on Sedimentation-Rate Its
Clinical Significance *Lancet* 1945 Oct 27 526-9 3 figs

The influence of temperature on erythrocyte sedimentation rate was investigated because experience suggested that the common belief that high external temperatures accelerate and low temperatures retard the rate was false. In the investigation the Westergren method was used with all technical precautions. Readings were taken every ten minutes, blood was withdrawn with as little venous stasis as possible, the patients having been kept fasting. Comparative determinations were made at 99°F and at 44°F. Preliminary experiments showed that previous chilling or warming of the specimens did not materially influence the rate in the actual determinations.

Of 483 miscellaneous cases examined 279 (57 7 per cent.) showed a higher sedimentation rate at 99 F. 109 (22 7 per cent.) showed a higher rate at 44°F and 95 (19 7 per cent.) showed less than 10 per cent. difference between the rates at the two temperatures at any stage during an hour. Thus the general statement that erythrocyte sedimentation rates are raised at higher temperatures is not correct.

In patients with hepatic disorders an increase in sedimentation rate at low temperatures was most pronounced, readings in the first 10 minutes often being more than five times as high in the cold as in the warm environment. In the

cold, the fall of the corpuscles was very rapid during the first 30 minutes slowing down only as packing prevailed. In all these cases the clumping of the erythrocytes into large visible aggregates was remarkable occurring usually a few minutes after the tubes had been placed in the cold. This phenomenon was very pronounced in a case of blackwater fever sedimentation being complete in under two minutes.

VENOMS AND ANTIVENENES

BOQUET P. Sur les propriétés antivenimeuses du sérum de *Vipera aspis* [The Antivenene Properties of the Serum of *Vipera aspis*] *Ann Inst Pasteur* 1945 Sept.-Oct. v 71 Nos. 9-10 340-43

The blood of the common viper of France is toxic but the symptoms it produces are not the same as those set up by the venom. The venom is a blood-coagulant and contains a phosphatidase enzyme capable of transforming lecithin into haemolytic lysocithin. The serum is haemolytic owing to its direct action on the red corpuscles and is not a coagulant and the toxicity of the serum is not affected by antivenene. Again, the serum when heated to 55°C. loses its toxicity but neutralizes the venom as strongly as the best antivenenes prepared by a long course of immunization of horses. It also neutralizes at least to some degree, the venoms of other Viperidae *Bilis aridans* *Cerastes cornutus* *V. russelli* and *Bothrops atrox*.

Venom and antivenene combine to form an insoluble product but the admixture of serum and antivenene does not result in any precipitation. Nevertheless the neutralizing property of the viper serum is derived from the venom. It is thought that a small part of the venom, in the course of its elaboration in the parotid, gains entrance to the blood like an internal secretion. This is at variance with the idea that a substance can be antagoneic only if it is foreign to the organism.

DERMATOLOGY AND FUNGUS DISEASES

BAGBY J W A Tropical Lichen Planus-Like Disease *Arch Dermat & Syph*
1945 July v 52 No 1 1-5 6 figs

The author states that since the beginning of the war numerous cases of a disease which in its clinical appearance is suggestive of lichen planus have been noted on some tropical islands of the Pacific. In some instances the disease begins as true lichen planus in others as a generalized erythematous exfoliating eruption the efflorescence of the primary lesions being followed by the appearance of localized lichenoid papules. A third group is described in which the primary lesions are bullae which are replaced by papules or nodules simulating hypertrophic lichen planus. Usually the distribution is generalized but in several cases the mid portion of the trunk has been free from lesions. The face scalp palms and soles may be involved also the tongue and buccal mucosae. As the eruption retrogresses pigmentation of the affected areas is noted in some instances the residual lesions are atrophic depressed deeply pigmented scars.

The clinical histories of five cases are recorded and details and illustrations of the results of histological examinations are given. All the patients were white men all except one—who was 27 years old—were aged from 42 to 47. Their period of tropical service had varied from 2 to 19 months. All except one had taken 0.1 gm of quinacrine hydrochloride (mepacrine) daily the exception had received this drug and quinine [doses not stated] for an attack of malignant tertian malaria which had subsided seven days before the eruption appeared. Most of the men had lost weight before the lichen developed. The author notes that the eruption tends to improve when the patient is en route to the United States he has not seen the malady in negroes. He adds the following comments:

1 Several men with lichen planus were seen in the eastern part of the Solomon Islands in 1943 but none with this atypical form was observed. Many more cases of this eruption have appeared in 1944 than in 1943 though the administration of quinacrine hydrochloride and the dietary allotments were the same for both years.

2. Various forms of lichen planus had been observed long before quinacrine hydrochloride came into use.

3 I have administered quinacrine hydrochloride to five men nearly well of the disease giving each three tablets daily for four days (admittedly a short trial) without causing a flareup of their lesions.

4 The eruption has none of the features usually associated with dietary deficiencies or with drug eruptions.

5 The disease has appeared in men who had been in the tropics for only two or three months in which period it is not likely that severe avitaminosis would occur.

[This paper is important as it is believed to be the first which has been published concerning a malady that has attracted the attention of military dermatologists and malarialogists serving in sub-tropical and tropical areas. Medical Officers serving with the British Forces have only recently been permitted to submit their observations on this disease for publication. It will be noted that whilst the author indicated that quinacrine hydrochloride is a common factor in all cases he does not attribute the eruption solely to this cause. Those interested in the matter may care to trace the following references: *Arch Dermat & Syph.* 1944 v 49 224 and 1945 v 51 353 also *Lancet* 1945 Dec. 1 711.]

R M B MacKenna

BERGER L. BEADRY M & GAUMOND E. Chromoblastomycosis due to a New Species of Fungus (First Canadian Case) *Canadian Med Ass J* 1945 Aug v 53 No 2, 138-42, 6 figs. [10 refs.]

The authors give a careful survey of the history of chromomycosis and describe a new case—the first example of the disease recorded in Canada.

The lesion of chromomycosis generally affects only one region—in 90 per cent. of cases it is on the lower extremity because of its greater exposure to trauma. In the Canadian case however the lesions were multiple and widely distributed. The granuloma appeared first on the web between the 4th and 5th fingers of the left hand and on reaching the size of a hazel-nut, it was excised after an erroneous diagnosis of prickle-cell carcinoma. A month later it reappeared and spread all over the dorsum of the left hand, while secondary granulomata appeared on the left forearm the right hand, the left foot the buttocks the right cheek and the right ear. The lesions consisted of thick warty cauliflower-like masses of pink, brown or violet colour with a more or less moist surface from the continual oozing of a foul-smelling exudate. Histologically the granuloma did not differ essentially from that seen in typical chromomycosis but the yeast-like form of the parasite in the tissues was relatively small, usually thin-walled and showed budding forms and chains of cells whereas the common fungi of chromomycosis (*Phialophora verrucosa* and *Hormodendrum pedrosoi*) appear in the lesion as thick walled cells often septate but never budding. In culture the fungus from the Canadian case grew freely on the common media used in mycology as brown or black yeast-like colonies of creamy consistency. The microscopic morphology of the fungus in culture presented the characters of the genus *Candida* but because of its black colour EDMONDS and CARRION considered it to be related to *Pullularia pullulans* (syn. *Dematiium pullulans*). The authors are, however, contented for the present to consider the strain as a black *Candida* like but still unnamed new species.

Treatment consisting of intensive iodine and X-ray therapy autovaccination with the fungus and local injections of arsenic and methylene blue was without avail. After two years of fruitless chemotherapy the lesions were removed by amputation electrocoagulation and scraping. The subsequent history of the case is not yet available.

J T DUNCAN

LEVY B M. Chemotherapy of Experimental Histoplasmosis in White Mice. *Amer J Trop Med* 1945 May v 25 No 3 241-51 8 figs. [47 refs.]

Up to the present time no drug treatment has been found effective in histoplasmosis—the following have been used without success—Fuadin Neostam sodium iodide neosphenamine bismuth pentnucleotide and liver extract sulphamillamide sulphathiazole sulphapyridine atabrine [mepacrine] Prototypin, potassium arsenite quinine, emetine Sulpharsenal, vitamins and other remedies.

As apparently no chemotherapeutic experiments had been made on artificially infected animals the author undertook this work and, using a freshly isolated strain of *Histoplasma capsulatum* he inoculated, intravenously 145 young white mice with the living culture. The inoculum was prepared by grinding up and suspending in sterile isotonic saline a seven-days-old culture on blood-agar at 37°C. consisting of the mixed mycelial and yeast forms of the fungus. The density of the suspension was adjusted to equal that of

No. 4 McFarland barium sulphate standard, and the infecting dose used for intravenous injection was 0.2 cc. Within 24 hours of inoculation treatment was started by injecting, by the peritoneal route appropriate doses of the following drugs in sterile solution—sodium iodide Neostam, Fuadin

sulphanilamide proflavin thymol B-9 (an organic iodide) and sodium propionate. All the animals in the eight groups developed histoplasmosis and in no case had the drug any observed effect on the course of the disease.

HEAT STROKE AND ALLIED CONDITIONS

BORDEN D L WADDILL J F & GRIER G S III Statistical Study of 265 Cases of Heat Disease. *J Amer Med Ass* 1945 Aug 25 v 128 No 17 1200-205 8 figs. [13 refs.]

This is an incomplete study of heat casualties occurring among troops undergoing training in a southern coastal area of the United States. In the summer of 1942 there were four fatal cases of heat stroke. In May to September 1943 265 cases of effects of heat (heat disease) were admitted to hospital [the total population at risk is not stated] there were three fatalities. For statistical purposes the cases seen in 1943 were divided into two main groups—mild and severe—but the proportion of the one to the other is not reported. An analysis of cases according to age, amount of training and home State—southern or northern—is given but the corresponding distribution of the total population is not stated. For treatment the division was into group 1—cases without circulatory failure and with cramps—and group 2—cases with circulatory failure. The former group is labelled by the authors Heat Prostration and apparently about 14 per cent of all the cases came under this category. The second and larger group were all regarded as exhibiting different degrees of the same pathological process. The milder cases showed mainly circulatory collapse and were called heat exhaustion. The more severe cases showed hyperthermia and were called heat stroke [it is not obvious that any real flash hyperpyrexias or heat strokes were seen though the history of one of the fatal cases is suggestive]. Nearly all cases showed some pyrexia.

The treatment of the group 1 patients was by rest and sedatives, cooling by water spray and by fan, water and salt orally in all cases and intravenous saline in severe cases. 0.9 per cent saline intravenously was found to be specific for the relief of cramps. In the group 2 patients who showed evidence of shock, plasma transfusions were given rather than saline to avoid the danger of pulmonary oedema, pure oxygen was given in all severe cases. Patients with definite hyperthermia were cooled by spraying and ice bags. All cases of effects of heat were considered to be emergencies and the patients were taken to a special treatment room immediately on admission, and later transferred to an air-conditioned recovery ward. [The Americans here are following the practice adopted by the British Army in Iraq in 1941 of having special heat stroke centres in all hospitals equipped with air conditioning and of having air-conditioned wards available for heat and other cases.] Pathological findings are not reported in detail here but are promised later. Post-mortem findings on three fatal cases in 1943 showed widespread petechial haemorrhages in brain, intestine, lungs and blood vessel endothelium and passive congestion in liver and lungs [similar findings have often been reported before].

The authors consider that all "heat disease" is due to heat accumulation resulting from inadequate evaporation when heat losses from convection, radiation and conduction are minimal owing to a high dry bulb temperature. They therefore believe that the wet bulb temperature is a good indicator of the probable incidence of heat disease, particularly at low wind velocities. They show charts correlating wet and dry bulb temperature and heat cases over the three hottest months of the year in support of this view. Accordingly in 1943 the physical activities of the troops in this area were limited on hot humid days and close order drill and severe training were stopped when the dry bulb temperature was 88°F or over and the wet bulb 77°F when the wind velocity was above 10 miles per hour or—if the wind velocity was below 10 miles per hour—when the wet bulb thermometer was 75°F or over. It is not stated whether this measure gave a reduced instance of heat casualties as compared with that in 1942. The troops were advised to drink 500 cc. of 0.1 per cent. saline each hour while at exercise in the heat and patients with heat exhaustion who gave a history of not taking the prescribed amount of salt were subjected to appropriate disciplinary action.

[This is a useful study but unfortunately it does not go into sufficient detail. The statistical information is inadequate and the account of the symptomatology is very compressed, e.g. there is no indication of the degree of pyrexia in the various cases other than that their temperatures were above 99.6°F. The association of symptoms is not considered at all. The promised pathological report should, however, be interesting.] W. S. S. Ladell

BLUM H. F. The Physiological Effects of Sunlight on Man. *Physiol Rev* 1943 July v 23 No 3 483-530 4 figs. [281 refs.]

The author's thesis is that all the evidence points to the physiological effects of sunlight on man being detrimental rather than beneficial. With the exception of the effect on avitaminosis D sunlight and even ultra-violet light is probably nothing more than a good placebo.

The spectral distribution of sunlight is from wavelengths less than 0.3 μ to beyond 2.1 μ . The distribution is affected by passage through the atmosphere—the ultra violet in particular is absorbed by ozone and small dust particles, hence there is most ultra violet all the year round in the tropics where the ozone is least and little ultra violet in the winter in temperate regions because the air mass is then greater and there is most ozone. The visible spectrum is not much affected by these factors, hence it may seem to the eye to be as bright at 5 p.m. as earlier in the day but sunburning which is due to the ultra-violet will not occur owing to the greater air mass through which the radiation passes. Similarly, a fine dust haze will screen off the ultra violet without any visible diminution in intensity. On the other hand, diffusion by dust and water droplets gives rise to sky radiation which is rich in ultra violet light so sunburning will occur on an apparently overcast day.

On reaching the skin up to 45 per cent. of the total sunlight is reflected if the skin is white but only 16 per cent. if it is black—the major portion of the rest is absorbed before it has penetrated more than a few millimetres. The maximum penetration is with wavelengths between 0.7 and 1.5 μ . HARDY found only 8 per cent. transmission of infra red radiation through two millimetres of human skin. With wavelengths below 0.32 μ transmission is also very low—the radiation is scattered by dead cells in the corneum and absorbed by the protein of the cells so none is transmitted and not much reflected. Radiation of wavelengths of 0.5 μ is not absorbed in the corneum—some is reflected and some gets through to the blood vessels beneath, where it is absorbed by the haemoglobin. Wavelengths of 0.6 μ are not absorbed by

haemoglobin and get through to subcutaneous tissues. Longer wavelengths than are found in the sun's radiation are all absorbed superficially. In the eye maximum transmission is of radiation at wavelengths 0.8μ . In general penetration is deeper and there is no scatter. The ultra violet is absorbed by the protein in the coats and media and in the infra red there is zero transmission with wavelengths 1.4μ owing to absorption by the water of the aqueous and vitreous but enough infra red can get through to the retina to cause burns—eclipse blindness. It is dangerous to look at the sun through glasses which filter off visible radiation only. The retinal pigment absorbs all radiation that reaches it.

Most of the radiation is absorbed non-specifically and heats the skin. Sunlight gives rise only to thermal sensations the greatest intensity of sunlight ($0.03 \text{ gm. cal cm}^2 \text{ sec}^{-1}$) is not sufficient to give rise to pain. The stimulus for thermal sensation is an alteration in the temperature gradient in the skin hence the infra-red which is absorbed superficially gives the best effect so radiation from a hot stove is a more effective stimulus than sunlight. Negroes, whose skins are better absorbers of sunlight have a lower sensory threshold to it than have whites. The radiant energy absorbed on the skin may raise the surface skin temperature above the body temperature especially if the circulation to the skin is diminished or stopped so that distribution of the heat to the rest of the body by the blood-stream cannot occur. The solar heat load on a naked body may be large and equal to the metabolic heat load of walking at 3 miles per hour. It is more for negroes whose skin does not reflect so much of the sun's radiation but in all cases it can be reduced by clothes. It does not vary much with latitude as there is only 20 per cent difference in intensity of the total radiant energy from the sun between the sun at zenith and the sun at 60° from zenith.

The chief photo-chemical effect of sunlight is sunburn. After about half an hour's exposure to sunlight (the exact threshold for intensity and for time varies greatly between individuals and at different times) there is a latent period after which erythema and a slight swelling develop. With longer exposures there is marked oedema followed by desquamation and blistering. Later the erythema gives place to tanning and finally the sun tan itself darkens with further exposure. The erythema is produced solely by rays of shorter wavelength than 0.32μ i.e. by ultra violet light. The time the erythema takes to develop varies with different wavelengths. No histological changes are found before the erythema appears. Blum considers that the first action of the ultra violet is on the cells of the Malpighian layer. Comparison between the action spectrum and the respective absorption spectra indicates either cell protein or nucleic acid as the light absorber. Blum favours the protein. There are some discrepancies explained. The ultra violet light produces in the cells a dilator substance which differs somewhat from the H substance. MENKIN (*J Exper Med* 1936 v 64 485) has called this leucotaxin. This substance diffuses down to the papillary vessels hence the latent period between exposure and erythema. Leucotaxin increases capillary permeability causing oedema and exerts a chemotactic effect stimulating the migration of leucocytes out of the vessels. This hypothesis is supported by the finding of an increased concentration of dilator substance in the skin and blood of animals after ultra violet radiation. The cells of the epidermis degenerate either owing to a direct effect of the ultra violet or according to Menkin (*Arch Pathology* 1943 v 36 269) as the result of the production of another substance necrosin. The longer wavelengths of the erythema spectrum may also penetrate far enough to have a direct effect on the papillary vessels. There is not yet any explanation of the continuation of the erythema for a long period without further exposures.

The erythema is replaced by sun tan. The sun-tan spectrum is the same as the erythema spectrum. First there is a migration of melanin granules from the basal cells to more superficial layers and then there is formation of fresh melanin in the melanoblasts. Though melanin can be formed *in vitro* by the action of ultraviolet light in the presence of ferrous salts on tyrosine this process requires more ultra-violet than can reach the basal cells in sunlight and cannot take place without free oxygen, whilst sun-tanning can occur in skin deprived of oxygen. BLOCH (*Zisch Physiol Chem.*, 1916 v 98 228 *Amer J Med. Sci* 1929 v 177 608) however finds dopa-oxidase in cells injured by ultra violet light and suggests that melanin is formed in them from L-dopa (laevorotatory β -3-4 dihydroxyphenylalanine) brought to them by the blood stream.

After the sun-tan has developed, radiations of wavelength up to 0.42μ cause a further darkening of the tan without formation of more melanin. This darkening occurs more rapidly than the initial tanning and may be due to oxidation of a reduced leuco-melanin as it will not occur in the absence of oxygen. This longer wavelength radiation is not stopped by glass and is also present in winter sunlight hence the retention of sun tan by some individuals throughout the winter. A similar darkening of pre formed melanin can be brought about by the administration of sex hormones.

A sun-tanned skin gives some protection against sunburn this is due primarily to a hyperplasia of the cells of the corneum after ultra violet irradiation, and the thick layer of cells that results shields the sensitive basal layer from further irradiation. When the corneum regains its original thickness most of the immunity passes off though the sun tan remains. There is, however some protection from absorption of the ultra violet light by the melanin which has migrated superficially this is the cause of the relative immunity of negroes to sunburn. In addition there is some cellular immunity to the action of ultra violet light which develops 12 hours after exposure. Sweat and sebum have no effect on the erythema threshold, but artificial protection against sunburn will be given by any substance that absorbs the wavelengths concerned, i.e. from 0.29 to 0.32μ .

The belief that exposure to sunlight can cause tumours comes from the observed greater incidence of cutaneous cancer among outdoor workers and on areas of exposed skin this belief is supported by the observation that malignant tumours develop in rats and mice after ultra violet irradiation. The carcinogenic rays are of the same wavelengths as the erythema rays. The action of the ultra violet light is either direct injury of the cells or the induction of somatic mutations by its action on nucleic acid. There is a discrepancy in that in mice the tumours are sarcomata whereas in man they are carcinomata this is explained by the thickness of human skin which is so great that the radiation cannot penetrate to the connective tissue beneath. Cutaneous cancer is certainly more common according to DOW (*Pub Health Rep Wash.* 1944 v 99 pp. 33 63 and 97) in latitudes where there is more ultra-violet thus at 41° the incidence in the United States of America is 23.1 per 100,000 but 9 further south it is 116.4.

The action of the ultra-violet radiation on certain steroid compounds to provide vitamin D in the skin takes place in the corneum, and considerable amounts of the vitamin may be lost in desquamating cells after irradiation. The release of leucotaxin or of some vasodilator substance is probably the cause of a fall in systemic blood pressure observed after sunburn and after irradiation from a carbon arc, which has a similar spectrum to sunlight. No direct effect of sunlight on metabolism and growth has been found. The sexual cycle of certain animals is affected by light probably because, with longer illumination, waking hours are longer and there is greater activity. COOK (*New*

York J Gynec & Obstet 1894 v 4 282) described suppression of menstruation in Esquimaux women during the dark Arctic winter but this has not been confirmed.

Excessive sunlight on the eyes causes photo-ophthalmia this is simply sunburn of the eyes. Very long wavelength radiation will produce cataract (glass blowers cataract) and also intense ultra violet irradiation of the lens might injure it and give rise to opacities but the high incidence of senile cataract in countries near the equator is probably not due to insolation.

Certain dyes and naturally occurring pigments have a photo-dynamic action when introduced into living systems they render the cells photo-sensitive so that oxidative processes usually injurious take place on exposure to light. Porphyrin pigments are photo-dynamic and as they may be derived from plants, grazing animals are sometimes affected, and this may be of great economic importance in some regions but man is rarely directly affected in this way.

Though sunlight is a major factor in man's environment it is not so by direct physiological action. It is easy to escape from a solar heat load by shade and suitable clothing and it is possible to avoid sunburn by simple precautions. The rôle of the sun in heat disease is thermal only there is no specific sun stroke effect. The biological success of the negro in the tropics cannot be attributed to his pigmentation because of the pigment the negro absorbs more solar radiation and has a greater total heat load than the white man under similar conditions he is however less sensitive to sunburn.

MISCELLANEOUS DISEASES

HYMAN A. S. Heart Disease in the Jungles of the South Pacific some Observations made among Melanesians of the New Hebrides and Solomons Islands Area. *Ann Intern Med* 1945 May v 22 No 5 630-52

The author who is well known as a cardiologist took advantage of an opportunity of examining Melanesian labour recruits to study cardiac disturbances among them and has written a paper of much interest. He found the incidence of arteriosclerosis to be unduly high as compared with European and American subjects. The men seemed to be 'old' at fifty and in many over 30 years of age tortuous temporal arteries were observed and radials were thickened. Blood pressure varied in a peculiar way in different localities in some the levels were low 80-90 mm. Hg systolic and 40-50 diastolic but in three islands [they are not specified] high readings up to 236 mm. systolic and 115 diastolic were observed in one tribe 11 out of 19 persons over 30 years of age had high pressures and one boy of 18 years gave readings of 160 and 104 respectively. Six out of nine with high pressure gave a history of previous blackwater fever and among the Native Medical Practitioners—a shrewd body of men—there is a current belief that blackwater fever is often followed by hypertension. Cardiac hypertrophy was another common finding for which no cause could be discovered.

Sinus arrhythmia and extra systoles were fairly frequently met with of murmurs the commonest were pulmonary systolic functional in nature and next apical systolic also classed as functional as no concomitant signs of heart disease were discovered. This may have been syphilitic in nature but was not so determined. Chronic coronary disease is common but often unassociated with pain, and even when there is pain it is comparatively slight and bears no resemblance to the acute angina pectoris of Europeans. Examination to

compare the pain threshold of the native with that of the white man revealed no difference in degree. Pain and oedema of the feet are found associated with vascular occlusion of the vessels of the leg and foot, which in turn are thought to be due to infections of the limb sustained in the jungle varicose veins are commonly seen, even in children, and "may have been due to secondary changes the result of continuous re-infection of the feet by various tropical organisms. [This is purely speculative and calls for further research, as indeed does the whole subject of cardiovascular disease among natives, and it is of particular interest in this region of the South Pacific where such lesions are common in one island but are rarely seen in others close by]

SANABRIA, A. & PLANCHART M., A. El factor carencial en la cirrosis hepática y en la miocarditis bilharziana. [The Deficiency Factor in Cirrhosis of the Liver and in Bilharzial Myocarditis.] *Rev Policlinica Caracas*. 1945 May-June, v 14 No. 82, 163-97 1 chart & 19 figs. [78 refs.] English summary (7 lines)

The authors start with a statement and consideration of the many reputed causes of hepatic cirrhosis which have been brought forward from time to time (race, sex, heredity alcohol, nutritional and toxic causes etc) with quotations from the literature of those who have suggested and supported these various theories. They conclude from all this that in hepatic cirrhosis nutritional deficiency plays an important part and that this deficiency is probably specific. They point out that cysteine and methionine exert a powerful action in the production of healthy liver cells and in preventing necrosis also that fatty infiltration of the organ is an important precursor of cirrhosis and that choline serves to prevent this Elsewhere it is stated that cysteine is harmful to the liver and may produce irregular proliferation, but that cysteine which in other circumstances provokes necrotic lesions of the liver is beneficial in the presence of choline inasmuch as the methyl groups resulting from the cysteine and the choline bring about the transformation of it into methionine. Hence the benefit which has been reported in cirrhotic patients from the use of choline chloride, with its lipotropic action.

Again, thiamin plays an active part only when it is converted into diphosphothiamin and patients with hepatic cirrhosis excrete much larger quantities of thiamin than do normal persons

Six cases are mentioned and a few details on each are given. Three [perhaps four] had ascites and four enlargement of the liver (in another the liver could not be palpated owing to the tenseness of the abdomen) four were passing ova of *Sch. mansoni* one had dysentery and two had positive Kahn reactions.

Benefit was reported in all from treatment with a diet of high protein liver extract choline chloride and mercurial diuretics together with a combination of vitamins A B and D [An elaborate scheme is presented in which more than a score of arrows point to chronic deficiency of vitamins, and there are several photographs of patients overexposed (in all senses of the term) so that they convey little information. The whole article to the abstracter at least, savours rather of special pleading and is not very convincing especially as so much is based on so small a number of cases.]

MAYER, J H Chronic Melioidosis. A Case showing Multiple Lesions of Bones, Joints, and Lungs. *J Bone & Joint Surgery* 1945 July v 27 No 3 479-85 5 figs. [14 refs]

This paper describes a case of melioidosis which is of particular interest in that it is the second to be reported in a European—a British soldier—and that

it ran a chronic course the majority end fatally in a few days or weeks. This case has already been reported by MAYER and FINLAYSON [this *Bulletin* 1944 v 41 694] The present account adds little to what has already been published
S P Bedson

ÖZTURA M H Ueber einen Fall von Morbus Behçet [A Case of Behçet's Syndrome.] *Ophthalmologica* 1944 Dec. v 103 No 6 283-92.

The patient a man aged 38 was under observation at a hospital in Istanbul from June to October 1943 he gave a history of having had recurrent attacks of the syndrome during the preceding four years At the hospital he was examined clinically by doctors of several special departments and various laboratory tests were made.

The symptoms were typical of the disease except that only one eye—the right—was involved the left remaining unaffected throughout the course of the disease

Cerebrospinal fluid was injected into two rabbits and three guineapigs, into the anterior chamber of the eye into the conjunctiva intravenously and intraperitoneally with negative results

Treatment with vitamins B₁ and C and sulphonamides had no effect

No cause was found virus-like elementary bodies have repeatedly been seen in Giemsa-stained smears of the aphthae in the mouth The diagnosis is made difficult by the fact that the three chief symptoms—aphthous ulceration in the mouth ulceration of the external genital organs, and the eye lesions (conjunctivitis corneal opacity hypopyon hyphaemia glaucoma) do not appear simultaneously but in irregular order in different cases. VAUGHN A M, HOWSER J W & SHROPSHIRE G Alnum (Dactylolysis Spontanea) Report of Two Cases from Illinois. *Ann Surgery* 1945 Nov v 122, No 5 868-77 8 figs. [10 refs.]

BERKOWITZ S Caterpillar Dermatitis. *Bull U.S Army Med Dept* 1945 Oct v 4 No 4 464-7

A species of caterpillar was found to be the cause of attacks of urticaria among the troops in New Guinea which sometimes almost reached epidemic proportions It occurred again in Northern Australia and was investigated. The caterpillars were allowed to crawl on the arms of 15 volunteers some developed local urticaria within a few minutes and this was replaced after 3 or 4 hours by a pruritic papular eruption which lasted for several days. Others had a discrete papular eruption which appeared after 6 hours and lasted for a few days to a week or longer Similar reactions were produced by rubbing the skin with the cocoons or the tuft of hairs at the tail of the female moth. When extracts of the caterpillars were placed on the skin no reaction occurred unless the skin was scarified, and patch tests with filtrates of extracts were negative. Caterpillar hairs soaked in various liquids for 24 hours still caused reactions as did baked hairs also but not hairs which had been pounded in a mortar

It was found from these experiments that the dermatitis is produced by the inoculation by means of barbed hairs of an unknown irritant The Australian caterpillar concerned is *Ochrogaster contraria* the name of the New Guinea caterpillar is not given. GENERAL PROTOZOOLOGY

KISKADDON R. M. & REMSHAW R. J. F. Human Coccidiosis. *J Amer Med. Ass* 1945 July 7 v 128 No. 10 731-2, 1 fig

In the stools of a man aged 60 suffering from ulcerative colitis, certain double-contoured cysts, measuring on an average 10×7 microns were discovered. The contents of the cysts were a granular protoplasmic material which showed no signs of further development though observed for months. The authors refer to the structures, one of which is shown in a microphotograph as cysts of *Isospora hominis*. (It is possible that they are undeveloped sporozoites of this parasite, but without evidence of their further development it is not justifiable to make even a diagnosis of coccidiosis much less one of *I. hominis*.) C M Wenyon.

KEAM B H., & GROCOTT R G. Sarcosporidiosis or Toxoplasmosis in Man and Guinea-Pig. *Amer J Path* 1945 May v 21 No 3 467-83 5 figs. on 2 pls. [41 refs.]

Cases of sarcosporidiosis in man fall into two groups. The first comprises those in which the parasite is large and enclosed by a striated capsule. The relatively large sporozoites are in groups separated from one another by septa. The characters are those of such well known sarcosporidia of animals as *Sarcocystis tenella* and *S. mieschkeana*. The second group includes those in which the parasite is smaller while the limiting membrane is thin and not striated. The sporozoites are smaller than those of the parasites of the first type and are not separated into groups by septa. The first case in which the parasite was of the second type was one discovered by Darling in 1909 in Panama. He realized that the parasite differed from the typical sarcosporidia but attributed the differences to the influence of an unusual host which man was considered to be. He fed guinea-pigs on infected mouse tissues and subsequently found similar modified parasites in these animals. The present paper describes the case of a woman in whom parasites of the second type were found in the heart muscle, and also records the discovery of similar forms in guinea-pigs which had not been subjected to experiment. It is concluded by the authors that in Darling's experiments the natural occurrence of parasites in his experimental guinea-pigs had not been excluded, so that it is more than doubtful that the parasites seen in the guinea-pigs represented modified mouse parasites. In the guinea-pigs parasites were found by the authors in the brain and kidneys as well as in the muscles. It is concluded that the cases in which the parasites are of the second type are more probably instances of toxoplasmosis than of sarcosporidiosis. In the absence of serological and inoculation experiments a final classification of the parasites cannot yet be made. C M Wenyon.

GENERAL ENTOMOLOGY

MADDEN A. H. LIMDQUIST A W & KIMPLING E F. DDT Treatment of Airplanes to prevent Introduction of Noxious Insects. *J Econom. Entom* 1945 Apr v 38 No. 2, 252-4

Tests were made in the laboratory, in an artificial cage resembling a part of an aircraft and in aircraft themselves, of the value of DDT as a residual insecticide. Four types of application were used—erosols combined with

pyrethrum dusts wet sprays and fine mist sprays—and evaluation of the treatments was made at intervals up to nine weeks by exposing mosquitoes and houseflies in treated airplanes for $1\frac{1}{2}$ to 2 hours and counting the insects that were down

A much more prolonged effect was seen in aircraft with upholstered interiors than in those with an all metal finish when aerosols and dusts were used [no comparative data are given for wet and fine mist sprays] In upholstered aircraft the knock-down with different applications was —

Aerosol (four or five times the recommended dosage) 42 per cent. after 3 weeks.

Dust (average dose 2 oz.) 100 per cent. after 6 weeks.

Wet sprays 5 per cent. DDT (300 ml. for an average fighter plane) 80 per cent. after 6 weeks.

Fine mist sprays 20 per cent. DDT (28 to 35 ml. per plane) practically none after 3 weeks

Fine mist sprays 20 per cent. DDT (400 ml. per plane) complete knockdown after 12 days.

The authors conclude that DDT is a useful adjuvant to normal spraying which it should greatly reinforce but not replace G Macdonald

LINDQUIST A W TRAVIS B V MADDEN A H SCHROEDER H O & JONES H A DDT and Pyrethrum Aerosols to control Mosquitoes and Houseflies under Semi Practical Conditions. *J Econom Entom* 1945 Apr 38 No 2 255-7

— MADDEN A H WILSON H G & KNIPLING E F DDT as a Residual-Type Treatment for Control of Houseflies *Ibid* 257-61

— WILSON H G SCHROEDER H O & MADDEN A H Effect of Temperatures on Knockdown and Kill of Houseflies exposed to DDT *Ibid* 261-4

Temperature exerts a marked effect on the rate of knock-down and the final mortality of flies exposed to treated surfaces. When exposed at a temperature of 70°F and transferred after being knocked down to a temperature of 80 F to 100°F they recover collapsing again when put back in a cooler climate and again recovering if warmed an alternation which can be repeated several times before death ensues. Similarly the time in which knock-down occurs varies directly with the temperature being more than twice as long at 95°F as it is at 50 F. Flies which had been in contact with a film at a temperature of 70°F never recovered if subsequently held at that temperature but some became active within an hour if they were moved to a temperature of 95°F or 100°F under which conditions the final mortality was usually less than 100 per cent. and this type of relationship between efficacy and temperature was shown to hold good under a variety of circumstances.

A solution of 5 per cent. DDT and 5 per cent. cyclohexanone in deodorized kerosene (*Deobase*) gave uniformly better results in terms of knock-down and mortality than a 5 per cent. solution in kerosene while solutions in dibutyl phthalate were inferior to those in kerosene.

Solutions and emulsions of DDT applied to screencloth at the rate of 100 mg per sq. ft. gave satisfactory mortality among insects brought into contact with it and did not injure the synthetic screencloth used in U.S. services the effect of emulsions lasted longer than did that of solutions in kerosene or dibutyl phthalate

Tests of the efficacy of DDT on different types of surfaces showed that suspensions had a higher toxicity when applied to inside paint than on unpainted wood and had least effect on full oil or outside paint. Kerosene solutions were relatively ineffective on any painted surface. DDT mixed with

cold water paints, such as calcimine, and applied at the rate of 25 mgm. per sq. ft. gave a slower knockdown than kerosene solutions applied to the surface, but remained effective throughout the test period of 44 days.

In the first paper the authors record the results of an enquiry into the practicability of substituting DDT for pyrethrum in apparatus of the pyrethrum-freon-aerosol type but much of the value of the work is lost as a result of their inability to quote the exact formulae used. DDT was found to be insufficiently soluble in Freon-12 to provide a satisfactory concentration without the use of an auxiliary solvent, for which purpose cyclohexanone was found most suitable. When DDT was used at concentrations 12.5 times as great as used for pyrethrins, the two were equally toxic to mosquitoes. Good results were obtained when they were combined in unstated proportions, and they were improved by the addition of motor oils of various, unstated, viscosities. G. Macdonald

LABORATORY PROCEDURES.

ATCHLEY J., BACON R., CURRAN G. & DAVID K. A Clinical Evaluation of the Copper Sulfate Method for measuring Specific Gravities of Whole Blood and Plasma. *J. Lab. & Clin. Med.* 1945 Oct., v. 30 No. 10 830-33.

A simple method of determining haemoglobin, haematocrit and plasma protein values from the specific gravities of whole blood, plasma or serum with

the help of charts was proposed by PHILLIPS *et al* [see *Bulletin of Hygiene* 1944 v 19 140] The present authors have tested its suitability for hospital practice

The copper sulphate solutions were in 50 cc amounts with specific gravities ranging from 1.008 to 1.075 by differences of 0.002 When 50 drops of plasma were added to these 50 cc amounts the average lowering of the specific gravity was found to be 0.0005

The constancy of the results was tested by determinations by two analysts of specimens of blood from 50 unselected patients in the medical wards the results were sufficiently uniform for clinical work The specific gravity determined by the copper sulphate method was compared with the determinations by the falling drop method of BARBOUR and HAMILTON (*J Biol Chem* 1926 v 69 625) and it was found that the agreement between the two methods was practically as close as between duplicates by either method. The serum protein determination was checked by the Kjeldahl method in 12 out of 14 cases there was agreement within ± 0.5 gm. per 100 cc. the other two showing differences of +0.7 and -0.8 gm. respectively

In normal and most pathological blood an approximate calculation of the haemoglobin can be made from the whole blood specific gravity alone if the mean normal value of the specific gravity of plasma is assumed to be 1.0264 In 47 of 50 cases the results were within 1.5 gm. of the figures obtained from the specific gravities of both whole blood and plasma and except in gross hyperproteinaemia the specific gravity of whole blood alone may be used to determine the haemoglobin and is reliable within ± 2 gm. per 100 cc.

The haematocrit values obtained from the specific gravity were compared with the direct determinations by the centrifuge the standard deviation between the two sets of haematocrit values in the authors' patients was ± 2.6 cc. of cells per 100 cc. of blood whereas that for the normal blood specimens of Phillips *et al* was only ± 1.2 ASHVORTH and ADAMS [this *Bulletin* 1942 v 39 164] found the mean deviation of gravity-calculated haematocrits from centrifuge haematocrits to be three times as great in series of pathological blood as in series of normal blood specimens in 51 of 53 cases the present authors found the gravity-calculated haematocrit values to be within ± 4.4 cc. per 100 of the centrifuge values the other two cases showed deviations of +9 and -8 cc. respectively A preliminary comparison of gravity and centrifuge haematocrit values would exclude this 4 per cent. of large deviations and then the gravity method could be used afterwards during the clinical course of the disease.

It was found that red cell counts could not be estimated sufficiently accurately from the haemoglobin in cases of anaemia for normal blood the equation is millions R.B.C per cu mm. = Hb (gm. per cent) $\times 0.325$ If the colour index is normal the rapid gravity method may be used to estimate changes in the cell counts during treatment

The other equations are as follows —

- | | |
|--|---|
| 1 Gm. protein per 100 cc. plasma | = 389.6 ($G_P - 1.0079$) |
| 2 Gm. Hb per 100 cc. blood | = 33.9 $G_B - G_P$ |
| | <hr/> |
| 3 Gm. Hb (approx) per 100 cc. blood | = 480 $\frac{1.0970 - G_P}{(G_B - 1.0264)}$ |
| 4 Haematocrit (cc cells per 100 cc. blood) = 100 | $\frac{(G_B - G_P)}{(G_B - 1.0264)}$ |
| | <hr/> |

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

KARK, S. L. & KARK, E. *The Practice of Social Medicine. Clin Proc* Cape Town. 1945 July v 4 No. 5 284-307

The principle of the Health Unit in countries in which the standards of the people are low or in which rural hygiene is rudimentary are not new but have not yet been as widely applied as they could be. The Unit with which the authors are connected was instituted at Pokela, Southern Natal, in 1940 (see this *Bulletin* 1944 v 41 611) and has now extended its activities so that 720 homes comprising about 5000 people are constantly visited by and have become well known to the staff.

The objects to which those who undertook this venture set themselves were not confined to the treatment and prevention of disease as those matters are generally understood by clinicians and public health workers. The element of social medicine, which involves close study of the homes economic position, mentality, beliefs, and characters of the members of the community was an essential part of the programme of work. It was not enough to know of the existence of disease and to cure it or to prevent it by public health action: the disease was rather regarded as one manifestation of a group of events or conditions, and it was held that elimination of that kind of disease in the future would not be possible so long as the basic conditions which gave rise to it or in which it could flourish, continued to exist. In such public health matters as water supplies and refuse disposal, of course this line of thought is not new: what is new in the work of this unit is the fact that attention is paid to many factors beyond those normally considered to pertain to sanitation. In this way curative medicine and public health activities were combined in one unit which practised social medicine in its full implications: only thus can that human understanding of the people be achieved which is necessary if medicine is to fulfil its purpose.

The Unit consists of a medical officer in charge, an assistant medical officer, "medical aids," nurses, health assistants and general labourers. It acts in close co-operation with the education and agricultural services in the area, and it conducts clinics, school medical work and routine visits to the homes of the people. In this way and by constant consultation and pooling of information, the home backgrounds become well known and the characters, habits, economic standards, movements and inter-relationships of the people are studied. Instances of the bearing of these factors on the health of adults and children are given in the form of detailed descriptions of homes and persons belonging to three families. The people are often illiterate and are strongly attached to belief in witchcraft. They are often lazy and make little attempt to improve their condition: they misuse their land, with the result that soil erosion occurs and crops are poor: *malnutrition is therefore common*. The men are often compelled to leave their homes for long periods, to earn money in the towns but some of them do not use the money to support their families. Alcoholism is common. In such circumstances there is considerable apathy and resistance to change of habits: by its educational and medical activities the Health Unit is gradually breaking down this poor and static mentality but the difficulties are very great.

To the reviewer it seems that the work of this Unit is admirably conceived. It must in time show to the people that the staff of the Unit has an interest in the welfare of each person as an individual, and it will gradually prove to them that the superstitions to which they are now so firmly attached have no basis in fact. This process will, no doubt, be slow but there is no valid reason why Africans should be more unable than others to rid themselves of such ideas.

The transition from an old tribal organization with its clearly understood loyalties and objects to a more modern and critical community must be painful and disappointing in that the removal of beliefs leads to cynicism unless they are replaced by progressive ideas equally strongly held. One of the most important of these ideas must be that the individual is valuable to the community and that the community welcomes whatever contribution the individual can make and is concerned to maintain the dignity of the individual. Here medicine impinges on the field of political psychology and organization as much as on that of economics. Medicine must more and more strongly insist that the health of the people depends to an enormous extent upon their mentality and economic status—that these in turn depend upon the level of general (and not only medical) education and political status improvement in which entails active co-operation between government and people for the benefit of both—and that if any one section of a population regards the protection of its health as a human right there can be no valid reason why that right is not common to all sections. There are indications that the South African Government appreciates the force of such arguments and that it is prepared to act upon them by the inauguration of schemes in which the state of mind of the African is given its proper importance and by which his economic status will be improved so that he will take a personal interest and pride in his own progress and welfare.]

PINTO C. Um ano de combate às doenças parasitárias que atacam os rodoviários da estrada Rio-Bahia 1942 a 1943 [Parasitic Diseases in the Labourers on the Rio-Bahia Road. One Year's Experiences during 1942-43.] *Mem. Inst. Oswaldo Cruz* 1944 June v 40 No 3 209-340 39 figs & 12 pls (11 folding). English summary.

The service created to cater for the people engaged in this road work was of considerable scope and comprised a central laboratory and an emergency hospital with transport for the sick. The organization is described in detail for which the original should be consulted.

The chief diseases encountered in these labourers were malaria, schistosomiasis, yaws, amoebiasis, hookworm infestation, scabies and the common infectious diseases. The commonest malaria parasite was *Plasmodium vivax* but *P. falciparum* was also often found and *P. malariae* infections are now reported for the first time from the State of Minas Geraes. Experiments on the control of spread of *Schistosoma mansoni* were made by the use of extracts of the stems or fruit of certain saponin-containing plants (*Serjania*, *Sapindus saponaria*) which contain 14 and 12.4 per cent of saponin respectively. These extracts are fatal to snails (*Australorbis glabratus*) and cercariae within a few minutes. An experiment to infect the hairy armadillo *Euphractus sexcinctus* with *S. mansoni* was successful. This animal was found to be naturally infected with *Ancylostoma caninum*.

GONZÁLEZ R. D. Algunos datos sobre la patología de la región de Tingo María. [Notes on Disease in the Tingo María District, Peru.] *Rev. Méd. Peruana* 1945 Feb v 18 No 194 33-68 4 figs [16 refs.]

Helminthic infestation is very rife according to the hospital laboratory records the incidence is 100 per cent. The commonest worms are *Ancylostoma duodenale*, *Trichuris trichiura* and *Ascaris lumbricoides*; one-third of the children are sent to the hospital by their mothers with a history of having vomited *Ascaris*. It is frequent to see 8-10 ova of hookworm and *Trichuris* in every field of the microscope. Intense hypochromic anaemia is common with

group follows with too little discrimination the results established in temperate regions. Nicholls adopts a position mid-way between the two and if the reviewer disagrees from certain of the conclusions of the book he wishes to make it clear that Nicholls has behind him a large weight of medical opinion in the tropics.

At present the field of nutrition in temperate regions is dominated by what might be called the optimal school of thought. To explain what is meant by this vitamin C may be taken as an example. It is common knowledge that the clinical disease, called scurvy is produced only when for many months a person has taken very low amounts of ascorbic acid. After the recognition of this fact the tests for sub-clinical scurvy were refined and it has been recognized that, although there may be no scorbutic haemorrhages the intake of ascorbic acid may be inadequate to ensure the speedy healing of wounds, and that other morbid conditions may arise. It is unfortunately true that it is quite impossible to say where this state of sub-clinical scurvy fades into normal healthy nutrition, and laboratory tests for saturation with vitamin C are probably artificial and yield fallacious results. Nevertheless, in view of all the known facts, nutritionists in temperate regions have agreed to advise an intake of ascorbic acid sufficiently high to guard against any reasonable fear of a deficiency. With our present spectacles we cannot detect the first signs of wear and tear that is the case for the optimal school of thought. The position of the present reviewer is that we should only lower these standards, fairly reasonably established in temperate regions to suit the inhabitants of the tropics when original observations, confirmed by several workers, suggest that there are certain racial or climatic variations peculiar to the warmer regions of the earth. It may well emerge that certain food constituents are needed in increased amounts in the tropics sodium chloride is a case in point others may be needed in decreased amounts, as calories to supply heat loss but these estimates must be based on original work conducted in the tropics. If there is not enough food in the tropics to give its inhabitants the diet they require and there is certainly not enough at the present time we may bow to necessity but we will never lower our conception of the truth.

Of all the food constituents required by man there is more certain knowledge concerning calorie requirements than anything else. Indeed in the question of calories we need not take the approach of the optimal school of thought too few calories will mean either loss of weight or inability to do hard work too many calories adequately absorbed will mean an increase of weight. Hunger and a sense of repletion maintain most of us in a delicately adjusted state of weight equilibrium. Let us see how the author approaches this problem.

The discussion of calorie requirements commences on pages 164-172, where it is broken up into two or three portions with paragraphs about protein and fat requirements in the middle. Under basal metabolism on page 165 there is no clear statement that B.M.R. depends on surface area none of the recognized formulae, such as that of Du Bois is given, so that B.M.R. cannot be calculated from a knowledge of the surface area which any given weight and height will produce. Nicholls states that a reduction of 10 per cent in the B.M.R. can be allowed for the inhabitants in the tropics, and indeed some reduction is fairly generally accepted, but no reference is made to original observations on this crucial point. There is no clear reference to the Specific Dynamic Action (S.D.A.) of foods, thus usually taken as about 200 calories in temperate regions which must be added to B.M.R. before the base-line to maintain body weight at rest can be drawn. On page 166 Lusk's estimate of the B.M.R. (no reference attached) is given as 1,680 calories for a 70 kgm. man in temperate regions. Incidentally if the height of this 70 kgm. man is 5 foot 11 inches then according to the Du Bois formula, B.M.R. (not including S.D.A.) would be about 1,800 calories. The former figure of 1,680 calories is

regarded by the author as too high and is reduced to 1 500 as most of the smaller races of the tropics are not 70 kgm in weight. Then follow the suggestions of the League of Nations Report (1936) advocating 2 400 calories for a man or woman living an ordinary life in a temperate climate but not engaged in manual work. This figure of 2 400 calories is reduced by the author to 2 100 calories (page 172) that is a reduction of 300 calories although the suggested reduction in B.M.R. for the inhabitants of the tropics (page 166) was only 180 calories. To this figure of 2 100 calories to cover ordinary everyday living the author adds 400-500 calories for the work of an average labourer in the tropics. No comment was offered on the League of Nations Report (1936) given on page 166 concerning the calorie requirements for work so that unless the mechanical efficiency of the labourer in the tropics is better than that found in temperate regions (usually in the region of 20 per cent like that of a petrol engine) then these 400-500 calories for work are adequate for 6 hours of light work, or 4 hours of moderate work, or 2 hours of hard work or $1\frac{1}{2}$ hours of very hard work. Some of us would like to add that in our experience the labourer too often in the tropics only does this amount of work and we have suspected that one of the main reasons is that he does not get enough to eat.

Protein requirements are far more generously dealt with in this book. An allowance of 65 gm is quoted on page 173 on the advice of a single authority and appears to be the final conclusion of the author. This conclusion is given as a small sub-section of a discussion on the calorie requirements. Previously the author gives without comment on page 166 the League of Nations (1936) recommendation of 1 gm. of protein for 1 kgm. of body weight in the adult. If the average weight of the labourer of Southern Asia is 52 kgm (page 172) then in the opinion of the reviewer 52 gm. of protein would appear adequate. As a matter of fact most of the discussion on protein requirements is given in chapter I pages 9-23 and it is difficult to understand from this section whether the author feels that the figure of 18.75 gm. of protein (page 14) is grossly inadequate or needs considerable addition. No final opinion is given in chapter I but one is referred at its end to dietary protein allowances in chapter IX. On referring to this chapter on page 156 one finds it misprinted chapter XI but in any case it refers only to condiments and beverages. The reference at the end of chapter I probably refers to chapter XI pages 167 and 173 but in any case one feels that the question of protein requirements has not been handled as a coherent whole.

The reviewer does not wish to stress the viewpoint of the optimal school any further especially in the less certain field of mineral and vitamin requirements. These are dealt with and their uses discussed in chapters II-VIII. The discussion is good and the facts are carefully recorded. Mention is made of the increased needs for common salt in the tropics in subsequent editions it will be possible to discuss the deficiency that arises in heat-exhaustion. The parts concerning calcium are good the author is of the opinion that an adult in the tropics may require 0.5-0.7 gm. and a child 0.5 gm. The latter is about half the amount usually suggested in temperate regions.

The anaemias found in the tropics are described on page 40 under iron requirements. Their classification on this page according to the colour index and cell diameter is based on a false premise namely that the colour index should always be exactly 1.0 and the corpuscular diameter should be exactly 7.2μ . Iron-deficiency anaemia and the liver principle-deficiency anaemias are classified, and as Nicholls suggests these anaemias are frequently combined. The reviewer has suggested that this combination might be called dimorphic anaemia the name however is not important, provided the combination is recognized but the author ascribes the term diphasic anaemia to the reviewer (page 45).

The vitamins are adequately and accurately described. Excellent tables on the analysis of foodstuffs are appended. The sections which deal with public health measures are some of the best in the book but more might be added on the dependence of improved nutrition on agriculture the prevention of soil erosion, the question of rents and methods of land tenure. In urban economy the question of a minimal scale of wages, and of feeding labourers as well as canteens at factories might all be added.

One hesitates to make suggestions concerning additions to a book but in future editions it might be wise to add sections on fluid intake (a neglected subject among nutritionists) and infant feeding on the breast or by the bottle. As a clinician the reviewer would welcome a clinical section in which first of all the classical diseases, such as beri-beri and pellagra are described. The modern tendency in books on nutrition is to append pellagra to the section on nicotinic acid but this strains the truth for pellagra is probably always a multiple deficiency disease. After this section on the recognized deficiency states there might follow notes on the less clearly defined conditions, the aetiology of which is unknown or uncertain, e.g. cirrhotic plasma protein abnormalities, crazy pavement dermatosis, deficiency bowel pattern. These are given, with considerable justification, as indefinite types of malnutrition on page 153. As one of these indefinite types there is given Barlow's disease but infantile scurvy is generally recognized and has a precise picture aetiology and treatment. The other indefinite types of malnutrition include "mandama, kwashiorkor, culebrilla, Gillan's oedema, pellagroid-beriberi. Those who have been interested in the kwashiorkor (misspelt kwashiorkor) syndrome of malignant malnutrition in Africa and the West Indies feel that it is probably premature to accord recognition to this syndrome in any textbook. We would like to see the very weighty reasons against its recognition presented fairly thus mandama (pages 284 and 296) is the name employed in Ceylon for what may be rickets. All the other terms on page 153 refer to the same clinical syndrome, described originally and accurately by Cecil (misspelt Cecil page 153) WILLIAMS on the Gold Coast as kwashiorkor. Future work on this syndrome may reveal that it is a mixture of deficiency states, or that it is semi-starvation or general malnutrition. Briefly speaking the difficulties in tropical Africa are very great the diets are grossly inadequate by any standard, including that advocated in this book yet little recognized malnutrition is present though much kwashiorkor exists. Whether it is present, perhaps considerably modified, in Asia must remain as yet an open question. Meanwhile oedema, crazy pavement dermatosis, diarrhoea (page 152) soapy stools (page 154) and fatty livers (page 154) appear to be common. These are all features of the kwashiorkor syndrome.

HETEROGENEITY OF STRAINS OF POLYMORPHIC TRYPANOSOMES ITS RELATION TO NATURAL AND EXPERIMENTAL TRANSMISSION

By J F CORSON O.B.E. M.D. D.P.H. D.T.M. & H.

Acting Assistant Director Bureau of Hygiene and Tropical Diseases

It is probable that every case or nearly every case of sleeping sickness is curable by Germanin in the early stage largely owing to the discovery of this drug better control of the disease is now possible than formerly. Sleeping sickness is still, however one of the most important and fatal diseases in tropical Africa as many infected persons are already in an advanced incurable stage when first treated.

Several important and interesting questions require further investigation the disease varies greatly in clinical severity in different areas being very acute where the Rhodesian form prevails and comparatively mild, in its early stage in Gambian sleeping sickness areas. These differences as is shown by the character of the infections in inoculated laboratory animals, are due to differences in the trypanosomes, some being more virulent than others. Differences in clinical severity are also found in a single area and may be attributed chiefly to differences between strains of trypanosomes as well as to differences in individual resistance in the population.

The incidence and significance of inapparent mild or chronic infections in areas where the disease is mainly acute seem worthy of investigation. The old problem of the relationship of the three so-called species of polymorphic trypanosomes to one another including the question of reservoirs of human trypanosomes in domestic and wild animals is an important one which needs further inquiry. A closer examination and analysis of strains of polymorphic trypanosomes than has hitherto been made is required.

Species of Polymorphic Trypanosomes

The three species of polymorphic trypanosomes are considered by most observers to be indistinguishable from one another morphologically but they show broad somewhat ill-defined physiological differences. *Trypanosoma rhodesiense* is only distinguished from *T. brucei* by being known to have infected man the two human trypanosomes *T. gambiense* and *T. rhodesiense* differ in degree rather than in kind in respect of certain qualities—the severity of the infection in man and animals sensitivity to arsenical and antimonial

compounds, the numbers of posterior-nuclear forms in animals their geographical distribution, and their principal insect vectors in nature. Both types of human trypanosomes are known to occur in the same territory though one or the other usually predominates, and strains with intermediate characters have been reported (LESTER, 1933). Whether they should be regarded as forming one species or two is still unsettled but however they may have originated, it is convenient to speak of them by separate names. It appears to be probable that mixed infections occur—*T. gambiense* and *T. rhodesiense* in man and either of these with *T. brucei* in animals—as there has been ample opportunity during the last thirty years for their introduction into each other's territories. No investigations of this seem to have been made.

Strains.

Laboratory strains of polymorphic trypanosomes are the descendants of samples taken from the blood (usually) of naturally infected persons or animals and their previous history is of course unknown but every strain when isolated, and at least for a considerable time afterwards must be regarded as being of heterogeneous composition. Although after repeated mechanical transmissions in small laboratory animals an originally polymorphic strain becomes less polymorphic, perhaps through selection with or without adaptive change the trypanosomes still show physiological differences and like all populations of living things except perhaps clones (descendants of single cells) the strain remains to some extent heterogeneous in composition.

All the trypanosomes of a human strain were of course able to infect or at least to live in the individual from whom the strain was taken—they were not at that time all necessarily able to infect other persons: and possibly none of them could infect certain very resistant individuals—in fact if such a strain of *T. rhodesiense* had been isolated from a naturally infected animal, for example a sheep or an antelope (infected from man by tsetse) and had been tested only on such very resistant persons, it would probably have been called *T. brucei*.

Selection

The question of what changes may be brought about in collections of living organisms by random sampling and special selection (apart from alterations in protoplasm) is an old subject. That selection must occur during the transmission of polymorphic trypanosomes from one host to another has naturally long been recognized—it is critically discussed by ROBERTSON (1929) in her paper (*vide supra*) on *Bodo caudatus*. When the sequence of events in cyclical transmission is considered, the importance of selection seems obvious, but it has not been definitely proved and should be investigated.

In the first vertebrate host the composition of the strain must be constantly changing—the numbers of trypanosomes in the peripheral blood are known to fluctuate at short intervals and the morphological picture (whatever significance this may have) also changes in respect of the relative proportions of the long and slender intermediate and short and stumpy forms of a polymorphic strain—relapse strains with different immunological characters are formed. Hence a single tsetse fly feeding on the same infected animal or man on different occasions would take up different samples of trypanosomes, and two or more flies feeding at the same time would not necessarily take up samples identical in composition.

In the tsetse fly also it is at least very probable that further selective changes in the strain would occur—in the same fly at different feeds, and in different flies, different numbers of trypanosomes, from none to many would survive

in the gut. Great differences are observed in the proportions of flies infected in experiments with the same strain of trypanosome and the same species of animal and tsetse—there are no doubt several causes of this but little is known about them. Similarly it is reasonable to think that the composition of a population of trypanosomes in the salivary glands of the tsetse fly must vary from time to time in the same fly and in different flies in a single experiment. By a modification of the method used by BRUCE and his colleagues (1913) BURTT (1943) has shown that a tsetse fly ejects in the act of biting different numbers of trypanosomes on different occasions—these quantitative differences may well imply qualitative differences also such as for example varying proportions of trypanosomes of high and low virulence and on some occasions no doubt none sufficiently virulent to produce infection in a host which on another occasion would be infected by the same fly (recorded in man by FAIRBAIRN 1943).

Finally the second vertebrate host would exert a selective influence on the strain when the fly bit it—some of the trypanosomes being able to infect it and others unable to do so.

From some experiments it was concluded that the infectivity of a strain depends upon the number of trypanosomes injected—by the syringe (KLIGLER & RABINOWITCH 1927) or by a tsetse fly (FAIRBAIRN 1943)—yet infection has often been produced by the injection of a single trypanosome and the greater chance of the inclusion of the most infective trypanosomes in the greater number—a qualitative difference might well explain the results. CORSON (1934) found no appreciable difference between doses of 200 and 100 000 trypanosomes of a virulent strain. The view that mere numbers affect infectivity may be correct but it has not yet been conclusively proved—the question might be decided by work with clones.

Individual differences among the trypanosomes of a strain are apparent in many laboratory experiments—trypanocidal drugs and sera for example do not kill all the trypanosomes simultaneously and often some trypanosomes survive as was frequently observed long ago (LEVADITI & MCINTOSH 1910). Some of the trypanosomes of a strain show greater sensitivity than others to light or ultra violet rays after treatment with acridine compounds (v. JANCsó 1931 1932 OESTERLIN 1936 HAWKING 1938)—relapse strains may be developed from survivors of the preceding strain.

It is therefore probable that selection plays an important part in the transmission of polymorphic trypanosomes in nature and in experiments.

Protoplasmic Changes

Apart from the effects of selection a strain may possibly undergo variation in course of time by actual protoplasmic changes in the trypanosomes—this has been shown to occur in other protozoa.

WENYON (1926) mentions evidence obtained by JENNINGS and by MIDDLETON proving that after long periods of multiplication definite inheritable variations do occur in the descendants of a single individual and this quite apart from any sexual process. It therefore seems probable that if the observations were continued for a sufficient length of time it would be possible to separate from the descendants of a single individual various races which would be as distinct from one another as the naturally occurring races. If this were not so it would be difficult to understand how evolution could take place at all. The subject is clearly dealt with by JENNINGS (1920) in a published series of lectures.

ROBERTSON concluded from her experiments on the action of acriflavine on cultures of *Bodo caudatus* that changes in the body of the protozoon were

produced, and found also that variation occurred in an untreated clone (the descendants of a single *Bodo*) during two years of culture.

JOLLOS (1921) exposed clones of *Paramecium* to arsenious acid and found that increased resistance to the chemical developed and persisted during growth in a normal culture medium for several months but it was gradually lost when the descendants of an isolated conjugating pair were tested it was found that the arsenic resistance had completely disappeared, indicating that the resistance was not a genetic change. In some cases however by long exposure to arsenic a fall in resistance occurred which since it remained after conjugation, was regarded by Jollos as a genetic change.

The loss by old laboratory strains of polymorphic trypanosomes of their transmissibility by tsetse flies appears to indicate an actual change in the trypanosomes.

Persistence of Changes

OEHLER'S (1913) experiments with a strain of *T. brucei* are well known—he made a clone resistant to salvarsan and carried it on by inoculation of single trypanosomes and the subclones were just as resistant as their ancestral clone. He mixed salvarsan-resistant and normal clones of *T. brucei* and inoculated the mixture from mouse to mouse and was able to distinguish the strains by testing with a solution of salvarsan, the normal trypanosomes being immobilized after many passages the resistant strain was crowded out by more rapid multiplication of the normal strain. He re-isolated the two strains from the mixed infection by inoculations with single trypanosomes. In these experiments there appears to be no selective process in the development of arsenic resistance.

Clones of trypanosomes were also used by v. PROWAZEK (1913) and by BROWN & BROWN (1937 1938 1939 1940) in their study of variation in *T. brucei*.

The loss of the kinetoplast which may occur spontaneously or be produced by the action of chemicals—oxazine, pyronin and other substances—has been regarded as an inheritable structural change. WERBITZKI (1910) found that within 24 hours after the injection of oxazine into a mouse infected with *T. brucei* 80-90 per cent. of the trypanosomes had no kinetoplast and in the case of pyronin 40-60 per cent. The peculiarity was retained through many mechanical passages in animals. WECK (1914) observed "blepharoplastless" [akinetoplasmic] forms in the blood of a waterbuck which was naturally infected with a polymorphic trypanosome while in the case of *T. evansi* also such strains may appear spontaneously in naturally infected hosts (HOARE & BENNETT 1937 1939). HOARE (1940) concluded that the akinetoplasmic condition can be interpreted as a mutation though it also bears some resemblance to cytoplasmic inheritance.

EBELICH and his pupils (1909 1911) and other workers more recently showed that resistance to arsenic can remain unchanged for years in strains of trypanosomes maintained by mechanical passages in animals while YORKE MURGATROYD and HAWKING (1933) proved that it could remain undiminished after two cyclical passages by tsetse flies. EAGLE and MAGNUSON (1944) reported the apparently spontaneous development of resistance to a group of arsenical compounds by a strain of *T. equiperdum* which had not been exposed to chemicals—they did not think that it was a change produced by selection, but that it resembled more a sudden overgrowth of the parent strain by a variant.

It seems therefore that the possibility of the occurrence of heritable change in trypanosomes cannot be excluded, but in a clone spontaneous changes would no doubt be very slow and probably negligible in short experiments.

Sexual Reproduction

It is the general opinion that trypanosomes have neither conjugation nor sexual multiplication by gametes the question is critically discussed by WEYON VANDERPLANK (1944) from observations on *T. rhodesiense* and FIENNES (1945) from a study of *T. congolense* concluded that sexual reproduction does take place. If this should be confirmed the subject of variation in trypanosomes would be still more complicated and the possibility of hybridization between the so-called species of polymorphic trypanosomes as was suggested by MANWELL (1936) for malarial parasites would at least need consideration

Positive and Negative Results

In transmission experiments with a strain of trypanosomes in which selection plays a part the retention of a character is a positive result in respect of the individual trypanosomes while the loss of a character by the strain is a negative result which could be explained as a loss by the strain of the trypanosomes possessing the character through random sampling or selection. The positive result shows what can happen e.g. the retention of infectivity to man after passages in animals whereas the negative result would not show that any trypanosomes in the strain had lost their ability to infect man as the trypanosomes infective to the volunteers used might not have been transmitted, having been weeded out by selection if the experiment were repeated a positive result might be obtained. In some experiments negative results have so little significance that they should be ignored.

Some positive results have been obtained in experiments with strains of polymorphic trypanosomes where cyclical transmission has been used. As mentioned above YORKE MURGATROYD and HAWKING found in one experiment that resistance to arsenical compounds was not decreased after two successive passages by tsetse flies. Strains of *T. rhodesiense* (DUKE 1935 CORSON 1937 1939 FAIRBAIRN 1943) and *T. gambiense* (VAN HOOFF HENRARD and PEEL 1943) have retained their infectivity to man after repeated cyclical passages through such animals (goats sheep pigs antelopes) as they would be expected to infect in nature. In these experiments the natural mode of transmission from vertebrate host by tsetse fly to vertebrate host was so closely reproduced that there can be no doubt that it occurs in nature although, so far none of the attempts to infect man with polymorphic trypanosomes obtained from naturally infected animals have succeeded there have been few attempts however in sleeping sickness areas

Validity of Conclusions

Conclusions and especially generalizations drawn from the results of experiments in which a strain of trypanosomes has shown changes in its characteristics are open to criticism on the ground of the possible effect of selection. Human strains have been stated to have become less or more virulent less polymorphic less or more transmissible by tsetse flies less or more susceptible to the action of drugs or sera even to have lost temporarily at least their infectivity to man. It was concluded from some experiments for example that there were indications that only a certain limited number of individuals of any tsetse population are able to act as hosts for trypanosomes yet in successive experiments with a certain species of reedbuck, 60 33 47 and 52 per cent. respectively of the tsetse flies which lived long enough to become infective had infected salivary glands. An explanation suggested for such an

exceptional result was that the blood of that species of reedbuck was very suitable for the development of the trypanosomes in tsetse flies—further investigations are desirable.

Only when a considerable number of transmission experiments with considerable numbers of flies and animals have produced uniform results may it be permissible to conclude that the trypanosomes have changed—have become say less virulent—this conclusion would apply to that strain and to the particular experimental conditions such as perhaps, the species of animal hosts. It might then reasonably be thought to have been due to the influence of the vertebrate hosts and if they were such as would be exposed to infection in nature the result might have some practical importance.

Uniformity of Material in Experiments

To test the validity of conclusions and especially generalizations drawn from transmission experiments with strains, it seems to be necessary to try to reduce the variable factors as much as possible. Variation in the vertebrate host could no doubt be much decreased by choosing an inbred strain of mice such as for example the *dba* (Little dilute brown) strain (see SNELL, 1942) and using sufficient numbers—a large mouse population would need to be kept and carefully inbred. Variation within a species of tsetse might possibly be somewhat diminished by using pupae from one locality, as different races are known to occur in different areas (BAX 1944). The use of clones of recently isolated strains of polymorphic trypanosomes would probably greatly reduce variation by eliminating selection. It seems to be the only way of analysing a strain of trypanosomes. Much could be learned, perhaps, about the effect of selection in transmission experiments by using normal and drug fast clones separately and in mixtures: arsenic fast trypanosomes (which are also acriflavine fast) could perhaps be followed through direct and cyclical transmission, and the same might apply to akinetoplastic trypanosomes in direct transmission. REICHENOW (1940) suggested that the kinetoplast may be essential for development in the tsetse fly. Such labelled trypanosomes might be recognizable in various ways—by testing with the drug to which they are fast by staining, or by measuring their photosensitivity—and might possibly be distinguishable from the "unlabelled" trypanosomes in mixtures, and the varying proportions at different stages of transmission experiments be observed. It would be interesting for example to work with mixtures of *T. brucei* and *T. rhodesiense* one labelled and the other not, also to isolate the most virulent clones of strains of *T. brucei* from say Zululand, testing them on man. How far technical difficulties or the behaviour of the clones might interfere with the success of such experiments would probably be indicated in preliminary tests.

These suggestions are offered partly because the ease with which tsetse pupae can now be brought to places outside tropical Africa enables such experiments to be made under good conditions in well-equipped laboratories.

I am indebted to Dr C. A. Hoare, Dr C. M. Wenyon and Dr Charles Wilcocks for helpful criticisms.

SUMMARY OF RECENT ABSTRACTS.*

III. MALARIA.

Epidemiology

RENNONEN (p. 821) discusses malaria in Finland, where the only vector is *Anopheles maculipennis typicus* and *mesicus*. Incidence curves show a remarkably consistent peak in May (as in Sweden, North Germany and Holland) and the height of this seems to be affected more by the temperature in April than by that of the preceding September—the explanation favoured is that in a cold April the people remain longer exposed than in a warmer April to the bites of overwintered mosquitoes. The author also thinks that the findings are inconsistent with the view that the spring peak is due to a prolonged incubation period after autumn infection.

PEREZ & PALAU (p. 171) describes the malaria position of the delta of the Ebro (Spain) where there is considerable cultivation of rice. *Plasmodium vivax* is the commonest parasite. The fact that at certain seasons relatively large numbers of labourers migrate into and out of this region, and may therefore disseminate their infections makes this a problem of more than local importance.

BUXTON (p. 335) has summarized what is known of the distribution of malaria and anophelines in Arabia—this cannot further be abstracted.

BOURGUIGNON (p. 172) notes that in the Elizabethville region of the Belgian Congo the chief vectors are *A. gambiae*, *A. fuscipes* and *A. maculipennis* (the last is not usually regarded as a vector of any importance and the author does not support his opinion by any detailed facts). The malaria of this region is almost all due to *P. falciparum* the local strains of which are very small. He discusses the seasonal incidence of the disease.

GARDNER (p. 959) reports outbreaks of malaria in a district in the highlands of Kenya (7,500–8,500 feet) where *A. gambiae* (the only vector) and other species of *Anopheles* breed, the former for short periods about May. The mean shade temperature is never high enough for the development of the parasite in the mosquito but *A. gambiae* spends most of its life in human habitations, where the temperature is 5–10° higher than outside. The temperature in these huts, about 66°F., is just high enough for the sporogony of *P. falciparum* in May.

BEET (p. 856) states that *P. ovale* infection is quite common in part of N. Rhodesia. JACKSON (p. 244) reports a case of *P. ovale* infection, presumably contracted in New Guinea where this parasite has not previously been seen.

JACOB and SWAROOP (p. 620) describe the results they have obtained by applying Gill's method of forecasting epidemics of malaria in the plains of

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 47. References to the abstracts are given under the names of the authors quoted, and the page on which the abstracts are printed.

the Punjab considerable precision is attained. In comment WHITE maintains that these predictions have had little value otherwise they would have been falsified more often by appropriate action.

RUSTOMJEE (p 684) describes the epidemiology of malaria in Ceylon, where it is common in the dry zone (*P. malariae* being pre-eminent) moderate in the intermediate zone (*P. falciparum* and *P. vivax*) and rare in the wet zone except for the epidemics which occur from time to time. These epidemics follow deficient rainfall which leads to drying of the rivers with the formation of pools in which *A. culicifacies* the only vector can breed. *P. malariae* plays no part in the epidemics. D ABRERA (p 959) has found that in Ceylon where during epidemics *P. falciparum* displaces *P. malariae* as the most common parasite valuable warning of an approaching outbreak may be obtained by charting the ratio between the two in the blood films examined.

PONS (p 335) has described the physical features of Indo-China in relation to malaria. The chief determining factor is the presence of *A. minimus* which breeds in the valleys of the mountain areas of the country. He claims that certain races of the inhabitants have adapted themselves to life in the unhealthy valleys and have developed considerable resistance to malaria other races have failed to do this.

Although the mortality rate for malaria in the United States was lower in 1943 than ever before FAUST *et al* (p 620) estimate from extensive blood film surveys that there are probably 400 000 infected persons mostly in the Southern States. They call attention to the possibility of spread as a result of malaria (especially *P. vivax*) in returned soldiers. WATSON and RICE (p 173) give an account of malaria as it has been observed in North Alabama during a period of 20 years. *P. vivax* is the common parasite but *P. falciparum* is not rare the mosquito concerned is *A. quadrimaculatus*.

Actiology

WOLFERS (p 85) has studied the structure and followed the course of development of *Plasmodium vivax* by means of the electron microscope. Details should be sought in the original.

It is often assumed that the paroxysms of *P. vivax* malaria have a periodicity of exactly 48 hours but YOUNG (p 686) shows that this is not true for some strains in two strains the periods were 43.4 and 45.7 hours respectively. The peak of fever coincides closely with the peak of young ring forms in the blood.

SERGIEV and TIBURSKAYA (p 622) have compared two strains of *P. vivax* one from northern and one from southern Russia by infecting two series of paretic subjects. The southern strain showed much lower parasite counts than the northern strain but more gametocytes and greater ability to infect mosquitoes (probably related to the gametocyte count). There was also some difference in resistance to quinine but not to mepacrine.

BENNISON and COATNEY (p 623) have been able to render sporozoites of *P. gallinaceum* and human blood containing *P. malariae* non-infective by exposure to X-rays.

RUGE and KREMER (p 85) observed abnormalities in malaria parasites which appeared in the blood in spite of suppressive mepacrine. These are described but the details cannot further be abstracted.

Transmission

GRUNDY (p 517) has compiled and brought up to date a list of *Anopheles* concerned with transmission of disease in man. References are given to the

authorities for the less well known species and in all, 99 species are included, almost all of which are implicated in malaria transmission. The other diseases concerned are filariasis and equine encephalitis.

EYLES (p. 435) sums up present knowledge on the range of flight and dispersion habits of mosquitoes. He gives a table of the maximum flight, so far observed, of 20 important vectors of malaria. In comment MACDONALD makes the point that work on this subject should be extended, since it has so practical a bearing on malaria control. [See also SHAPIRO *et al.* RUSSELL *et al.*, and HUFFAKER & BACK, below.]

GALVÃO *et al.* (p. 4) discuss the rearing and maintenance of mosquitoes in the laboratory in a paper which should be consulted in the original.

RAEVSKY (p. 858) after criticizing the methods used for estimating the numerical fluctuations of a mosquito population, describes his own method, which entails a census of all buildings capable of sheltering mosquitoes and periodical mass collections, or collections in representative sections of the community. He elaborates the uses to which these data can be put.

GEIGY (p. 684) has shown that larvae of *A. claviger* (*bifurcatus*) may survive winter in Switzerland, in frozen ponds and slow streams. He has demonstrated that repeated feeding on a gametocyte carrier results in higher infection rates in mosquitoes than a single feed.

A careful investigation of the anophelines of the Dead Sea area of Palestine by SHAPIRO *et al.* (p. 247) has shown that *A. multicolor* breeds in brackish water puddles (2.5 per cent NaCl) near the shore, in spite of the nightly rise and daily fall of the water level which causes the disappearance of these puddles during the day. The larvae were found 10-15 cm. below the gravel surface in the daytime. *A. sergenti* breeds in swamps fed by springs and though breeding is most prolific from spring to autumn, it continues throughout the winter. Strong evidence was found that *A. sergenti* travels from 4½ to 8 kilometres even the males disperse for long distances so that their presence does not necessarily indicate the proximity of breeding places. *A. superpictus* and *A. multicolor* breed in the same swamps but *A. sergenti* is the predominant species.

SHUTE (p. 857) has made counts of the number of sporozoites of *P. falciparum* in the salivary glands of infected *A. maculipennis atroparvus*. The numbers vary greatly up to 219 450. If the mosquitoes are allowed to feed on a rabbit every two or three days after the estimated time of first infection of the glands, the numbers of sporozoites in the glands are fairly well maintained for 25 days, after which they decline but there is no uniformity in the discharge of zoözoites.

Little is known of the mosquitoes and of the incidence of malaria in Iran. BEKLEMISHEV and GOSTAEVA (p. 248) studied the subject in 1941 in the north-western part of the country. In the uplands *A. superpictus*, *A. maculipennis maculipennis*, *A. sacharovi* and *A. claviger* (*bifurcatus*) are found especially in well-watered country in which standing collections are allowed to form. In the Caspian coastal area, where the climate is sub-tropical, drainage ditches and rice fields are numerous, and *A. maculipennis* and *A. hyrcanus* are found, but in the rivers, where the fish *Gambusia* is present, larvae are not found. GUTSEVICH (p. 533) names the anophelines found in northern Iran. *A. sacharovi* and *A. superpictus* are important in relation to malaria, but *A. hyrcanus* is also found.

BIELOGLAZOV (p. 249) reports the wide distribution of *A. maculipennis messasi* throughout the Mongolian People's Republic.

An account of the biology of *A. algeriensis* is contributed by ENIKOLOPOV (p. 859). It is not an effective carrier of malaria, though it feeds on man, its mean duration of life being much less than that of *A. maculipennis* usually too short for the complete cycle of development of the parasite.

SAUTET and MARNEFFE (p 336) describe the outdoor resting places of certain anophelines of Lebanon and of the Niger country

MATTINGLY (p 434) has produced new keys to the anophelines of West Africa.

RIBBANDS (p 3) has studied the mosquito which was formerly regarded as the *melas* variety of *Anopheles gambiae* and concludes that the evidence justifies its classification as a separate species *A melas*. This mosquito will breed in water of high saline content. CHWATT (p 860) has studied the morphology and habits of *A melas* in relation to *A gambiae*. The morphological differences in the various stages are not in his opinion sufficiently clear-cut to permit the classification of *A melas* as more than a biological race of *A gambiae* from which it differs mainly in its ecological preferences and geographical distribution. RIBBANDS (p 245) has studied the effect of rainfall tides and periodic fluctuations on a population of *A melas* in Sierra Leone. This mosquito breeds in brackish grassy areas flooded only at high tide and mostly dry in the dry season and in brackish *Avicennia* mangrove areas. The average size of the adult population is closely determined by rainfall and peaks occur 20-30 days after the causative rainfall. Increase is also correlated with high tides in the dry season. *A melas* is present throughout the year but the population in the wet season is ten times as high as it is in the dry season and the influence of tides is not so great as that of rain.

LEWIS (p 246) has studied *A gambiae* around Wadi Halfa with a view to its control first as a protection to the town itself and second for the purpose of creating a barrier which the mosquito (whose breeding is confined to the vicinity of the Nile) cannot pass, so that if it can be eliminated from Egypt north of Wadi Halfa there would be little risk of its infiltration again from the south. *A gambiae* breeds in pools among the islands of the cataract on sandy banks in the river and near its margin these dry up and breeding in them ceases from December to April but the mosquito reappears in April probably because it has continuously been breeding in the cataract area. Control by oiling Paris green and drainage has proved successful and the larvorous fish *Gambusia holbrooki* has its uses.

Working in Brazil in 1939 DE OLIVEIRA CASTRO (p 960) found by experiment that the eggs of *A gambiae* do not survive long if kept away from water even in a moist atmosphere. Survival is rather longer at 14°C than at higher (room) temperature but even then only 0.1 per cent. of the eggs produced living larvae when they had been kept for 20 days at 14°C away from water.

By means of the precipitin test MARNEFFE *et al* (p 247) have found human blood in 55 per cent of female *A gambiae* tested in the Middle Niger region.

WANSON and BERTEAUX (p 337) have found salivary gland infection in *A brunneipes* near Léopoldville. It is not a common mosquito and is therefore not an important carrier.

COVELL (p 623) has contributed a comprehensive paper on the distribution breeding places adult habits and relation to malaria of the anophelines of India and the Far East. Of the many species which have been described 41 are concerned with malaria in these areas and the paper deals only with these. They are classified as—12 important vectors, 16 of local importance and 13 having probably no practical importance. During the war the two groups which have been outstanding in relation to malaria are the *fluviatilis minimus* group in India, Burma and S China and the *punctulatus* group (with *moluccensis*) in New Guinea and the S W Pacific.

PURI (p 85) has issued a revised edition of his synoptic tables for the identification of full-grown larvae of the Indian anophelines.

D ABRERA (p 337) describes the eggs of a number of anophelines of Ceylon the original should be consulted for details.

SIDDONS (p. 624) in India has succeeded in infecting 9.4 per cent. of *A. culicifacies* with *P. malariae* and in transmitting the infection by bite to a healthy subject. He found a much higher infection rate in those mosquitoes which were fed in the period August to February than in those fed in March to July when the weather is hot—in those fed in the colder weather the gland infection rate was 34.4 per cent. The extrinsic incubation period varied from 22 days at 70°F to 14 days at 80°F. In the man who was infected by the bite of some of these mosquitoes parasites were first seen in the blood 30 days after the infecting bite, and the first attack of fever occurred 36 days after infection. Following the account of this work is a paper by the same author (p. 625) in which he shows that the optimum temperature for development and transmission of malaria parasites in *A. culicifacies* is 70°-86°F provided that humidity is fairly high. Development of *P. falciparum* and *P. vivax* does not take place above 94°F. The extrinsic incubation period for *P. vivax* is 7 days at 86°F.

RUSSELL *et al.* (p. 637) have performed a large experiment on the flight range of *A. culicifacies* in India. The greatest observed distance was between 1.5 and 1.75 miles in some cases against the wind. The authors have treated their results statistically and for details the original should be consulted.

JASWANT SINGH and JACOB (p. 618) have investigated malaria on the southern coast of the Bombay Presidency. Here the disease is not common on the coastal belt but is hyperendemic in the foothills and the interior. The distribution coincides with that of *A. fluviatilis* the only vector of which, in one place, 11 per cent. were found to be infected—it breeds in slow running streams. *A. culicifacies* and *A. annularis* were also found, but there was no evidence that in this area they act as carriers of malaria. *P. malariae* is the most prevalent parasite.

In part of Hyderabad State where an irrigation project has been in existence for some years, the chief vector is *A. fluviatilis* which here breeds in irrigation canals, rainwater pools and seepages. *A. culicifacies* probably plays a small part in transmission. In this area ABRAHAM and SAMUELS (p. 619) found *P. malariae* to be the commonest parasite. A control programme which aims at destruction of adult mosquitoes, larval control, and the use of suppressive quinine has given encouraging results.

VISWANATHAN *et al.* (p. 623) note that most freshly-fed *A. fluviatilis* leave their places of feeding before dawn, for some outside resting place. This affects the spray-killing of adults as a method of control, and the authors advocate daily spraying where there is no larval control, or spraying twice a week where larval control exists or on 2 consecutive days with 2 days rest, in the period September to November when the proportion of the mosquitoes which leave the dwellings at night is highest.

A. philippinensis is the only important vector in the deltaic region of Bengal, where the maximum transmission season is from September to November. IVENGAR (p. 625) shows that it favours human dwellings as daytime resting places, and that control should include spray-killing. This species breeds in ponds of clean water and is inhibited by shade. It does not usually breed in rice fields.

KNIGHT and FARNER (p. 638) give reasons for thinking that *Anopheles punctulatus molestus* should be known as *A. p. farneri*.

REEVES (p. 437) has carried out precipitin tests on blood from the stomachs of freshly engorged American anophelines of various species.

Hess and HALL (p. 626) note that *A. quadrimaculatus* breeds only in waters on which there is abundance of vegetation or floating material, and have classified the plants which are important in malaria control, from this point of view in the area concerned. SCHOOF *et al.* (p. 628) have shown that larvae

and pupae of *A. quadrimaculatus* and *A. punctipennis* can survive for some days in mud but the precise length of time is not known. BURGESS and YOUNG (p 437) give the results of their investigations into the handling and feeding of *A. quadrimaculatus*. For details the original should be consulted. HUFFAKER and BACK (p 687) have found that *A. quadrimaculatus* does not usually move in significant numbers more than one mile from its breeding place but exceptional circumstances may permit it to do so. A very few individuals may travel 3 miles.

In the Annual Report issued jointly by the Government of Trinidad and the Rockefeller Foundation (p 617) the point is made that *A. aquasalis* is an important vector but that it is strongly zoophilic in habit. It seems that the presence of buffalo stables near a village has a strong effect in keeping down the incidence of malaria in the inhabitants and it is suggested that traps baited with animals may be used in malaria prevention. In the wetter parts of Trinidad transmission is effected by *A. bellator* which breeds in the bromeliads which are parasitic on the shade trees of cocoa plantations. Suggestions are made and experiments have been carried out on the removal or destruction of these plants.

COCHRANE (p 86) has produced circumstantial evidence of some weight that *A. argyritarsis* may be a vector of malaria in Grenada.

BEVIER (p 614) states that *A. darlingi* is the only known vector of malaria in the coastal belt of British Guiana, and that in 1943 it accounted for 96 per cent of all anopheline captures. It almost completely disappeared in the drought years of 1938-41 but reappeared with the heavy rains of 1942-43. It does not seek acid or brackish waters. With the increase in the abundance of this mosquito there was a corresponding increase in the amount of malaria for which *P. falciparum* was largely responsible though *P. vivax* and, to a smaller extent *P. malariae* were found. GIGLIOLI (p 615) also states that *A. darlingi* is the only vector in Georgetown British Guiana where it breeds extensively in the suburbs. It disappeared during the drought but its reappearance after the rains caused an epidemic of malaria. *A. darlingi* breeds in the drainage system of a cemetery and in rice grounds and cane fields; its eggs die in water containing more than 0.6 per cent of NaCl. Where malaria is abundant *P. falciparum* and *P. vivax* are common but during the drought when malaria was rare most of the infections were due to *P. malariae* rarely seen in times of epidemics.

UNTI (p 86) has studied the viability of eggs of certain anophelines of Brazil, when kept in moist earth.

Larvae of certain S. American anophelines die when the dissolved oxygen content of the water is reduced to 1.5 p.p.m. UNTI (p 86) concludes that pollution of water with organic matter by decreasing the oxygen content may be an efficient and economical anti-larval measure. The same author (p 87) has failed to find any correlation between the iron content of water and anopheline breeding.

Transfusion Malaria

MCCLURE and LAM (p 627) report two cases of transmission of *P. malariae* by the transfusion of blood which had been refrigerated for 5 days. The two donors were Sicilians who had lived for 30 years in the United States, and who presumably had not been infected there.

OFFICER (p 688) has shown by experiment in man that the routine course of anti-malaria treatment given to a recipient immediately after transfusion of malarial blood prevents the disease. In cases of emergency therefore a potentially malarial donor may be used for transfusion.

STOHLMAN (p. 174) reports the transmission of *P. vivax* from an infected patient to three donors of blood transfused directly to him, without storage. There must have been some reflux of blood through the apparatus used. In comment MOLLISON points out that direct transfusion is now very rarely used, but adds that transmission from donor to recipient is possible even when the blood has been stored for some days.

Tests.

SOBERÓN y PARRA (p. 174) describes an intradermal test for malaria in which the antigen is prepared from the blood of a fowl heavily infected with *P. gallinaceum*. The results indicate a large measure of specificity.

HEIDELBERGER and MAYER (p. 689) have found that an antigen prepared from normal human red blood cells is as effective as (and more readily available than) the antigen prepared from *P. gallinaceum* in the complement-fixation test for malaria. By this test 28 per cent of sera from malarial patients were positive.

BOGEN (p. 861) describes a test which depends on the fact that serum in malaria is precipitated by a stock buffer solution diluted with four times its volume of distilled water. This test is strongly positive during and for some time after an attack. It may be useful in diagnosis or for epidemiological investigations, and in prognosis.

WOOD (p. 250) has found that the red cell sedimentation test provides a useful means of differentiation between malaria (in which the rate is high) and infective hepatitis (in which it is relatively low) in their early stages.

ROSENBERG (p. 440) has investigated six serological tests for syphilis, to determine their relation to malaria. He concludes that, of all the generally accepted tests, the Hinton test gives the smallest percentage of false positive reactions in malaria. That malaria can often be distinguished from syphilis by the pattern of positivity of tests and that persistence of positive reactions beyond 6 weeks, in the absence of continued malarial infection, should arouse suspicion of syphilis. POTTER *et al.* (p. 690) tested 100 men, suffering from malaria (99 *P. vivax*) with the Wassermann and Kahn tests. All had previously given negative results, and were presumably free from syphilis, but 12 were now positive and 10 doubtful. The results all became negative within 30 days (the patients presumably having received anti-malaria treatment).

The sera of a high proportion of patients with malaria were found by COLEMAN (p. 250) to contain the V_1 agglutinins of *Bact. typhosum* in high titre. This may be because the parasite possesses a V_1 antigen or the reaction may be anamnestic.

SHEPHERD (p. 4) has devised a radiological technique for demonstrating the spleen without the use of any contrast medium. Measurement of the size of the spleen can thus be made and the method may be useful in relation to malaria.

Pathology

RIGDON (p. 699) has found evidence that infarcts of the spleen in *P. falciparum* infection may result from obstruction produced by hyperplasia of cells in the walls of the venous sinuses to which leucocytes and red cells may adhere.

MARSHALL (p. 438) reports a case of spontaneous rupture of a malarial spleen without any history of trauma. Attention is drawn by KERR and VORRIS (p. 341) to the fact that the liver becomes enlarged, and shows other (biochemical) signs of involvement in half of the patients with malaria. This may occur in a first attack, and is not a sign of chronicity.

DÄHNE (p 338) has found that reticulocytosis occurs in malaria patients who are anaemic about one week after treatment has been started. The blood sedimentation rate is high in such patients but not in patients who are not anaemic.

Clinical Findings

HUNT (p 5) relates his experience of malaria in West Africa and in North Africa. In the latter subtertian infection was much more alarming and demanded intravenous quinine therapy much more often than in West Africa. He emphasizes the fact which is so often forgotten and relearned at a cost that subtertian malaria is a dangerous disease which mimics other conditions to the confusion of the unwary. It should never be lightly regarded.

FERRIMAN (p 438) writes of his experience in West Africa of 2,000 cases of malaria in white R A F men most of whom had never before been exposed to the disease. Almost all the infections were due to *P. falciparum* but pernicious attacks were not common, suppressive mepacrine (0.2 gm twice a week) being enforced. Positive blood slides were not found in all cases and the author comments on the value of splenomegaly as an aid in diagnosis. Sub-clinical malaria was not uncommon the chief symptom being recurrent headache this was relieved by anti-malaria treatment.

HYMAN (p 962) gives a list of mistaken diagnoses made in 100 men whose illness was subsequently found to be malaria during the early days of the campaign in the Solomon Islands. These were chiefly diagnoses of cardiac pulmonary and abdominal conditions but arthritis diseases of the brain or other parts of the head kidney thyroid and scrotum were also diagnosed. Later an outbreak of dengue added to the difficulty of diagnosis.

GAYID (p 5) notes that in the Middle East *P. vivax* infections were frequently atypical. He gives details of the standard quinine-mepacrine pamaquin treatment adopted in that area.

In the province of Voronezh Russia which at one time in the war was under German domination STEINBERG *et al* (p 339) have found that malaria in children frequently runs an unusual course regardless of the species of parasite which may cause it to be mistaken for other diseases. This may be due to importation of new strains or to alteration in virulence as a result of serial passage through undernourished human hosts. KASSIRSKY (p 628) refers to the fulminating type of *P. vivax* infection which has previously been described in Russia.

BOYD (p 175) has studied the parasite density in persons with naturally induced *P. vivax* malaria, at different stages of the infection. Great variation was observed, for details of which the original abstract should be consulted.

GORDON *et al* (p 692) describe the clinical features of relapsing *P. vivax* malaria in soldiers evacuated from the South Pacific. The strains showed a pronounced tendency to relapse but the attacks were relatively mild and were easily controlled by mepacrine. In rehabilitation the development of physical fitness and the restoration of self-confidence were important.

BOYD and KITCHEN (p 174) give details of their observations on the renewal of clinical activity in naturally induced *P. vivax* malaria both after spontaneous remission and after remission due to administration of drugs. The facts presented are so numerous that further condensation is not possible.

From an experience of the course of malaria in British troops who escaped from Italy into Switzerland, ANDERSON *et al* (p 961) conclude that the influence of a high altitude climate (Adelboden 4,300 feet) is very beneficial in the relapsing benign tertian type.

MCGINN and CARMODY (p 341) describe 16 patients with cerebral malaria, all ascribed to *P. vivax*. FITZ HUGH *et al* (p 340) describe cases of cerebral

malaria among troops stationed in India, noting several cases in which the infection was due to *P. vivax* or *P. malariae* though the majority were due to *P. falciparum*. In a well-nourished group previously in a high state of physical fitness the death rate was much lower than in another group of lower standard though the incidence did not greatly differ. The association of convulsions and coma carried a grave prognosis especially if the parasite count was high on the other hand, in some fatal cases there were few demonstrable parasites. VISWANATHAN (p. 691) discusses the pathogenesis of cerebral malaria, and describes several fatal cases in which a well-formed ante-mortem clot was found in the sagittal sinus. This, he thinks, has not previously been reported.

DAS GUPTA and GANGULI (p. 338) describe a fatal case of *P. falciparum* infection in which large numbers of gametocytes in all stages of development, and of schizonts, were present in the peripheral blood.

In Panama, APPLEBAUM and SHRAGER (p. 176) have investigated 125 cases of pneumonia associated with malaria, chiefly in young white men. The pulmonary lesions were most commonly lobular in distribution. The combination was not severe. In one group the condition yielded to sulphonamide treatment, but in another it yielded to anti malaria treatment alone. In most of the sputa examined no pathogenic organisms could be found.

ROBERTSON (p. 439) writes on lesions of the eye in relation to malaria. The most common is ulcer of the cornea, often with recurrent iris but optic neuritis and amblyopia have also been found.

MERRILL (p. 691) has observed patients in the United States forces who having had malaria, complain of chills which they attribute to malaria but which are not accompanied by fever and which are of psychogenic origin. ARBUSE (p. 963) makes the point that although neuropsychiatric symptoms may occur in malaria, they are usually consistent with the personality of the patient, and are activated by that disease as they may be by other organic diseases.

HARVEY (p. 963) describes a type of peripheral neuritis associated with *P. vivax* malaria, which was quite common in one large American military hospital.

HARRISON and DAKIN (p. 176) report a case of nephrosis, associated with *P. malariae* infection, in the south-west Pacific. It is not certain that the malaria was responsible for the condition, but it is not unlikely.

MANSON BARR and MUGGLETON (p. 434) record a case of unusually long persistence of *P. ovale* infection.

KEAR and SMITH (p. 338) note that if the inhabitants of Panama survive childhood they are unlikely to die of malaria. The number of parasites in the peripheral blood is not a good index of the severity of the case.

Charles Wilcocks

[To be continued]

RABIES.

A REVIEW OF RECENT ARTICLES. XLIV*

(i) Virus

BAILEY¹ points out that there is scarcely any "organic liquid, humour secretion excretion or parenchymatous pulp" of which the action on the virus of rabies has not been investigated but, curiously enough, as far as he

For the forty-third of this series see this Bulletin 1945 v 42, p. 674

¹ BAILEY J. Action de l'extrait de pancréas sur le virus de la rage. *Bull Acad. Méd.* 1945 v 129 Nos. 13 14 & 15 233-7

could determine no one had thought of studying the action of pancreatic juice. The author points out (and he has apparently been considering mainly the possibility of proteolytic action) that if he had been able at the time he thought of carrying out his investigations to procure some of Northrop's crystallized preparation of trypsin he would have used that. He decided to use a watery extract of pancreas from a dog and he outlines his method of preparation, which was carried out at low temperature. After the extraction had proceeded for a period of 48 hours he tested the amylolytic effect of the maceration on starch and since such activity was demonstrated he believed he was justified in his surely hazardous assumption that it would possess proteolytic activity. His virus suspension consisted of a 1:50 suspension of brain of a rabbit inoculated with a fixed strain of virus. This suspension had been filtered through filter paper to remove the larger particles of tissue. The author states that a number of experiments were performed along similar lines and he has recorded the results of some of these as being typical. Two sets of tubes were put up in each experiment one containing the virus suspension and equal parts of the pancreatic extract and the other the virus suspension with adjusted (somewhat crudely) by the addition of sodium carbonate but he does not state clearly what indicator he used. The recorded pH values of the mixtures ranged between 10 and 12 and were stated to be similar in the control tubes. The mixtures were kept at 10°C for 24 hours. The results of two experiments are recorded in one 4 mice were inoculated with the mixture of virus with pancreatic extract and 2 with the virus in saline and in the other 5 guinea pigs were inoculated with the pancreatic-extract virus mixtures and 2 guinea pigs with the control mixture without pancreatic extract. The 4 mice and 5 guinea pigs inoculated with the virus-pancreatic-extract mixtures survived and the 2 mice and 2 guinea pigs inoculated with virus alone died of rabies. The author concludes that the virulence of brain suspension was destroyed by the aqueous extract of pancreas of a dog in 24 hours at 10°C. He also made some experiments in which he states that the recorded pH values of the several mixtures of virus with or without pancreatic extract ranged between 6 and 8.4 (in one of these experiments a street strain of virus was employed instead of a fixed strain and in the other the strain is not stated). In these tests also only a limited number of animals were inoculated with the mixtures a total of two rabbits and four guinea pigs with the mixtures of pancreatic extract and virus and one rabbit and two guinea pigs with the virus mixtures and all the animals died of rabies. The author concludes from a consideration of all the results that since the destructive action of the pancreatic extract on the virus of rabies was dependent on the alkaline reaction of the medium this shows that it was due to the activity of trypsin and that the destructive action on the virus was proteolytic in nature. [Some of the details of these experiments have been stressed because it is felt that it would be unfortunate and misleading if they were subsequently referred to as conclusive evidence of the destructive action of a pancreatic extract (or trypsin) on the virus of rabies. Surely it would be necessary to make such studies on a quantitative basis especially as regards the relative virus content of the original suspensions (a gradocol filtrate should be preferable) and the control mixtures without pancreatic extract at such a high alkalinity as pH 11 or 12. The stability of the virus in media of different pH values should form the subject of a preliminary investigation. It might quite well be that the amount of virus surviving in certain hydrogen ion concentrations is low and if few test animals are inoculated the probability of detecting virus would be a question of chance. The optimum pH value for tryptic activity is less alkaline than pH 11 to 12 and although trypsin would be to a certain extent protected by

[March, 1946]

protein in the substrate one would expect the activity of trypsin to be much reduced above pH values of 8-9.]

KAMAZAWA (this Bulletin 1937 v 34 671) WEBSTER and CLOW (ibid and 1938 v 35 168) BERNKOPF and KLIGLER (ibid 1938, v 35 641 and 1941 v 38 494) and SCHULTZ and WILLIAMS (ibid 1938 v 35 641) reported the successful cultivation of fixed strains of rabies virus in relatively simple media consisting of fragments of rabbit mouse rat or chick embryo brains in Tyrode's solution. Whereas KAMAZAWA did not add serum to his medium, WEBSTER and CLOW incorporated 10 per cent monkey serum and BERNKOPF and KLIGLER recorded that they found the addition of human or monkey serum, but not rabbit serum, to be favourable to the multiplication of the virus. Subsequently WEBSTER (this Bulletin 1938 v 35 646) KLIGLER and BERNKOPF (ibid 1939 v 36 723) and HODGE WEBSTER and LAVIN (ibid 1941 v 38 181) reported on the antigenic value and potency of vaccines prepared from such tissue cultures. The virus potency of the tissue cultures or dogs infected intracerebrally with fixed rabies virus. The last-named authors therefore attempted to increase the virus content of the tissue cultures by several methods without success but they obtained a 10-fold concentration of the culture virus by freezing and drying. WEBSTER and CASALS (this Bulletin 1942, v 39 82) stated later that from a practical point of view culture virus had not proved a satisfactory source of rabies vaccine due chiefly to its low virus content.

In later experiments on the vaccination of mice and dogs WEBSTER and CASALS (this Bulletin 1941 v 38 498 and 1943 v 40 201) reverted to fresh brain material from mice and dogs infected intracerebrally with fixed rabies virus as a source of antigen for vaccine production. (It is interesting to note that PLOTZ and REIGAS this Bulletin 1942 v 39 589) reported the successful cultivation of street strains of virus in culture media consisting of chick-embryo brain tissue in Tyrode's solution with monkey serum and chicken plasma.)

PARKER and HOLLENDER¹ now bring confirmation of the possibility of propagating "fixed" strains of rabies virus in tissue cultures similar to those used by the earlier workers. They have extended the observations of the latter and have recorded a number of interesting findings. They used different strains of "fixed" virus that had been passaged 12 times in mice the Alabama strain 128 times and the Squibb strain 109 times. The Alabama strain gave the best results in that the cultures appeared to have a higher virus potency but as the technique was modified in the later experiments which were made with the Alabama strain only it would be difficult to associate these results with any special attribute of this particular strain. Finely chopped embryo mouse brain was used as the tissue component of the medium one large brain or its equivalent being used for each culture. In the early experiments the fluid phase of the culture consisted of heated rabbit serum (1 hour at 56°C) (constituting $\frac{1}{2}$ or $\frac{1}{3}$ of the final mixture) or of ox serum ultrafiltrate (1) (see SOKORS and SANDERS, Arch Pathology 1942, v 33 619) together with 1.4 per cent sodium bicarbonate (1) and Tyrode's solution containing four times the usual amount of glucose. The pH of the mixtures was adjusted to 7.2, by means of a gas mixture before the tissue was added, and thereafter the cultures were gassed with a mixture of

¹PARKER R. C. & HOLLENDER, Augusta, J. Propagation of Rabies Virus in Tissue Cultures. *Proc. Soc. Exper. Biol. & Med.* 1945 Oct v 60 No 1 94-8 [Rats 12 footnotes]

oxygen (21 or 80 per cent) carbon dioxide (8 per cent) and nitrogen. In the later experiments the fluid medium consisted either of heated rabbit serum or ox serum ultrafiltrate (4) combined with Simms's 1/7 solution (see SIMMS and SANDERS *loc cit*). As an indicator of pH all cultures contained either 0.001 per cent or 0.005 per cent phenol red. Another feature of the later experiments was that the culture tissues were ground when passages were made. It had been found by comparative inoculation tests in mice for virus potency with ground and unground tissues that grinding is necessary in order to liberate the main bulk of the virus from the tissues. There was little to choose between the two methods of grinding with quartz sand or with Tenbroeck grinders. In all the later experiments 125 cc Erlenmeyer flasks were used, whereas in the earlier experiments Carrel flasks with only 3 or 4 cc. of medium were used.

Comparative tests with cultures containing heated rabbit serum or on the other hand, ox serum ultrafiltrate showed that beyond the sixth passage in which passage the rabbit serum cultures had a higher titre than the ox serum ultrafiltrate cultures it was not possible to detect any appreciable difference between the two sets of cultures. A duplicate series of cultures incubated for nine passages at 35°C and 37°C respectively showed no consistent difference in the amount of virus produced.

Comparative tests showed also that the subjection of the cultures to continuous gassing with the mixtures of O₂, CO₂ and N₂ had no real advantage provided that the buffering system in the medium is capable of maintaining the pH value at an optimum level [this optimal level is not stated]. The results of other experiments showed that embryo mouse brain culture virus could be maintained in cultures prepared from the brains of 5-day-old mice; the brains of 14-day-old mice were less satisfactory and the brains of 28-day-old mice [48-day-old mice in the summary] were quite unsuitable. [No mention is made of any attempt to propagate virus recovered directly from the brains of infected mice in cultures with 5-day-old brains.] Unsuccessful attempts to propagate the rabies virus in chick embryo brain cultures are recorded. The source of the virus in these experiments was either virus passaged in mice or in mouse embryo brain cultures or mouse virus adapted to chick tissue by several intracerebral passages in chick embryos in eggs. In all experiments two passages of 3 and 4 days respectively were made each week.

In early experiments with the Squibb strain the virus was successfully passaged 57 times during a period of 28½ weeks at the 41st passage mice were infected with a 10⁻⁶ dilution of the culture tissue but by the end of the experiment the limiting infective dilution had fallen to 10⁻².

Three experiments two of seven passages and one of eight were made with the Webster strain of virus but at the end of the experiments the limiting infective dilution of the cultures was not higher than 10⁻⁴. In one of the later experiments with the Alabama strain, with which the most satisfactory results were obtained 19 passages were made and in the protocol of the experiment it is stated that at the 19th transfer (passage) the culture virus killed mice at a dilution of 10⁻⁶ whereas in the summary and conclusions the authors report that the virus multiplied to the extent that mice were killed regularly by the culture material in dilutions as high as 10⁻⁶. It is not clear whether this represented the limiting infective dilution of any culture of the series or whether some culture passages had somewhat lower virus titres. In the early passages in mouse embryo brain cultures of another series with the Alabama strain, limiting infective dilutions (see Table I) of 10⁻⁴ to 10⁻⁶ are recorded. It would be interesting to know also what the virus titres of subsequent culture passages (if any have been made) prove to be. (The virus titres of the cultures in the experiments with the Squibb strain

appeared to be relatively good up to the 41st passage but later deteriorated very much.)

In the experiments with the "Alabama" strain the limiting infective dilution of the original virus in mouse brain was not determined, but all four mice inoculated with a 10^{-7} dilution contracted rabies.

(ii) Symptomatology and Diagnosis

RIFKIN *et al.*³ record that rabies had never been known to exist on a certain large island in the Pacific which came to be used during the war as a base with an important harbour and greatly increased shipping. Dogs were introduced from the mainland and at first it was thought that rabies had been brought in also. This suspicion arose when two dogs which had been kept as pets suddenly became excitable and vicious, had epileptic fits and also bit six marines. Inclusion bodies which were considered at first to be similar to Negri bodies were found in sections of the brains of these dogs, but no animal inoculation tests were made. A course of Pasteur vaccination treatment was therefore given to the marines. Later a limited number of guinea-pigs, rabbits and mice were inoculated with brain suspensions of dogs showing similar nervous symptoms, but no rabies developed in these test animals. The incidence of dog distemper on the island was very high and the clinical pictures of the nervous cases were identical with those recorded in rabies. A veterinary surgeon who was a member of the team brought four cases of nervous distemper for investigation, and inclusion bodies similar to but not characteristic of Negri bodies of rabies were found in sections of their brains, trachea, bronchi and bladders. Inoculation of guinea-pig, mouse and rabbit with suspensions of brain gave negative results. The inclusion bodies could be found in the ganglion cells of the cerebrum, mid-brain, medulla and in the Purkinje cells of the cerebellum. They were found in sections of the medulla and *Cornu Ammonis* of the first two dogs referred to above. They were about 2-10 μ diameter, oval in shape, stained red with Mann's stain and in certain cases had a vacuolated structure but without internal granulations as seen in rabies. The authors cite a reference in 1943 to the occurrence of such inclusion bodies in the brain and other organs of dogs infected with distemper and point out that their occurrence might lead to a mistaken diagnosis of rabies if animal inoculation tests are not made also. The inclusion bodies under discussion, which are associated with cases of nervous distemper in dogs, are commonly known as Lentz bodies. They were first described by that author in 1907 (*Cent. f. Bakt., 1 Abt. Orig.* v 44 374). Descriptions of these bodies are found also in papers by BARTS and STAROVICI, 1912 (*m C R Soc Biol.* v 73 229), SINIGAGLIA, 1913 (*Pathologica* v 6 107) and KAKTOROWICZ and LEWY, 1922 (*m Arch. wiss. prakt. Tierhik.* v 49 137) and others. GREEN and EVANS, 1939 (*m Cornell Vet.* v 29 35) recorded their occurrence in the tissues of foxes, mink and ferrets infected with distemper.]

RODRIGUEZ⁴ has compared results obtained in diagnosing rabies by histopathological methods with those secured by inoculating groups of five mice with suspensions of brain tissue from the suspected cases of rabies. The former methods included examination of smears and sections for Negri bodies and examination of sections of different parts of the central nervous system, including the medulla, the ganglion nodosum of the vagus and sympathetic

³ RIFKIN H., CERADA, E. B., ZARROW, M., HENDERSON, D. G. & WHITEHEAD, J. O. The Diagnostic Significance of Inclusion Bodies in Rabies and Canine Distemper. *J. Lab. & Clin. Med.* 1945 Sept. 30 No. 9 748-51.

⁴ RODRIGUEZ H. H. Sobre el diagnóstico histopatológico de la rabia. *Bolet. Inst. Bact. Chile* 1943 Oct., v 2, No. 3 111-30 3 figs. [23 refs.]

ganglia such as the stellate ganglion for the several infiltrative and degenerative lesions originally described by BABÈS (*Ann Inst Pasteur* 1892 v 6 209 and *C R Soc Biol* 1908 v 64 284) GOLGI (*Berlin Klin Woch* 1894 v 31 325) RAMON CAJAL and DALMARCO GARCIA (*Bull Inst Pasteur* 1905 v 3 298) and in nerve ganglia by VAN GEHUCHTEN & NELIS (*Ann Med Vet* 1900 v 49 243).

In all 200 cases were examined comparatively and it was reported to the author that rabies virus had been demonstrated by the inoculation of mice in 119 of these no virus was demonstrated in 81 instances. By the combined examination for Negri bodies in smears and sections and for the infiltrative and degenerative lesions rabies was diagnosed in 115 of the cases and negative results were recorded in four i.e. a percentage error judging by the mouse tests of 3 per cent. The percentage errors recorded were when the diagnosis was made by examination of smears alone for Negri bodies 27 per cent. by examination of sections for Negri bodies 20 per cent. and by the combined examination of sections and smears for Negri bodies 15 per cent. The infiltrative and degenerative lesions were intense in 79 per cent. of cases and moderate in 21 per cent. Forty-eight of the cases reported to be negative by the histopathological methods were definitely so and thus was a percentage of 59 per cent. of the 81 cases reported to be negative in the mouse tests. Thirty-seven were recorded as doubtful and four of these were diagnosed as rabies by inoculation of mice.

(iii) Pathology

NEUJEAN^{*} reports that during the last three years he had to examine numerous dogs to determine whether they were infected with rabies. The procedure adopted which was considered very satisfactory was to inoculate suspensions of the brain into rabbits and mice and to examine sections for Negri bodies. He had been struck by the polymorphism of these bodies and the irregularity of their distribution. In addition the author noted the existence of small forms like dust dispersed outside the nerve cells among the nerve fibres and in certain cases ramified filamentous forms resembling a mycelium, which were difficult of interpretation.

He had been impressed by a suggestion of BRUMPT in 1938 in relation to the possible re-classification of the viruses of vaccinia and rabies which he now regards as prophetic. In view of these preliminary observations he tried culture methods which had been successful for growing rickettsia and he claims to have demonstrated the presence of the parasite of rabies by haemoculture. He describes the technique as being surprisingly simple. The blood from animals infected with rabies was collected in the presence of liquoide (Roche) [liquoide is described in the literature as a preparation of sodium polyanethol sulphonate for use in culture media to prevent coagulation and to abolish the bactericidal power of the blood]. In the beginning this blood was sown into two media Tyrode and Tyrode with 1/1000 agar. The examination of these media which had been sown with the blood suggested suspicious images only. However on examining the blood liquoide which remained after the sowing of the media he found an intense multiplication of corpuscles presenting all the characteristics morphology tinctorial affinity and structure of the corpuscles met with in rabies from anhistic bodies to noticeably vacuolated corpuscles and bodies usually called Negri bodies—from the limit of visibility to giant forms. Such multiplication was detected when the blood liquoide had been kept at about 25°C for 3 to 4 hours. Examination of the blood was carried out by taking a loopful and

^{*} NEUJEAN G. Mise en évidence par hémoculture du parasite de la rage. *Rec Trav Sci Méd Congo Belge* 1945 July No 4 139-41.

making smears which were stained by the May-Grünwald-Giemsa method or by Lestouard's method. The author states that the use of heparin or sodium citrate as anticoagulants appeared to hinder multiplication of the parasite which was found only with difficulty and showed profound morphological changes.

Positive haemocultures were recorded with blood samples collected in advanced stages of the disease from four rabbits infected with the Pasteur "fixed" strain of virus and from one rabbit and one dog inoculated with a street strain of virus. No attempt appears to have been made by the author to correlate the presence of the parasite with the infectivity of the blood for susceptible animals by intracerebral inoculation. He intends, however, to secure further information on the time of the appearance of the "corpuscles" in the blood in relation to the course of the disease and more convincing evidence may be forthcoming. [Confirmation of these observations is necessary. At this stage it is difficult to comment on what has not yet even reached the stage of being *sub judice*. The results reported would seem to be at variance with the irregular results reported in the literature in attempts to demonstrate the presence of the virus of rabies in the circulating blood but the methods employed up to the present may have been inadequate.]

(iv) *Methods of Treatment and Statistics*

CECCALDI⁶ reports that two fixed virus strains are maintained by rabbit passage at Brazzaville. One is the Pasteur strain which was passaged 21 times during 1943 and the other is the strain "jeune chien" of Brazzaville which was also passaged 21 times in 1943 and was in its 24th passage. Recently for the production of vaccine the Pasteur strain has been inoculated into sheep. This was necessitated by the shortage of rabbits and the need to produce relatively large quantities of vaccine. [A similar procedure has been forced on a number of other Institutes during the war period.] The virus is maintained entirely in rabbits: the sheep are inoculated for vaccine production only four times during the year. The vaccine up to November 1943 was prepared by the Semple method from 1 per cent. cerebral tissue with 0.05 per cent. carbolic acid, and was then changed so that the concentration of brain was 5 per cent. and of carbolic acid 1 per cent. The vaccine is considered to maintain its efficacy for a period of three months if kept in the cold. The opinion now held is that the rabies virus which occurs in French Equatorial Africa is normal in virulence and that bitten people should be treated by the same methods as those applied in Western Europe and other parts of Africa. Ten strains of street virus were recovered during the year eight from biting dogs, one from a horse and one from a human being who died 21 days after the commencement of treatment 24 hours after a severe bite in the deltoid region. Negri bodies were demonstrated in the brain of the human patient and a street strain of virus was recovered. The case of the horse is described in detail but no history of a bite is given. Negri bodies were found in the horse's brain but they appeared to be infrequent and were small in size.

The chief interest in the report for 1943 by DURIKUX⁷ of the activities of the Pasteur Institute in French West Africa is to be found in the observations on the results of vaccination of human beings against rabies since decentralization of the service was instituted in 1937. During the years 1938 to 1942, 1 122 patients were treated and four deaths occurred before the end of the

⁶ BRAZZAVILLE [A. E. F.] RAPPORT SUR LE FONCTIONNEMENT TECHNIQUE DE L'INSTITUT PASTEUR EN 1943 [CECCALDI, J. Director] 21-33. Page.

⁷ AFRIQUE OCCIDENTALE FRANÇAISE. RAPPORT SUR LE FONCTIONNEMENT TECHNIQUE DE L'INSTITUT PASTEUR EN 1943 [DURIKUX, C.] pp. 43-53. Service de la rage.

vaccine treatment. The decentralization would appear to be especially advantageous in cases of severe bites. Previously treatment was not commenced in some instances until 12 days after the bite. On the other hand decentralization when carried too far might have disadvantages. In outlying districts it is considered better to transport the patient to the centre where the vaccine is kept than to await the arrival of the vaccine which might lose activity in transit. The opinion is expressed that the dose of vaccine for children should be the same as for adults unless they are nurslings for whom it could be reduced slightly.

(v) Neuroparalytic accidents

KOENIGSFELD* reports that a patient aged 43 years was bitten by a dog on 1st January 1944. Anti rabies vaccine treatment was commenced at once and 10 cc of vaccine was given over a period of 14 days. The vaccine prepared according to Semple's method consisted of a 5 per cent suspension of the brain of sheep infected with the Pasteur (Paris) strain of fixed virus. During the period of vaccination and contrary to advice the patient consumed alcohol but only in moderate amounts. Immediately after the last injection of vaccine the patient complained of severe headache pains and numbness in the thighs and arms blurred vision restlessness and complete insomnia. A retrobulbar neuritis of both eyes was detected and there was absence of abdominal reflexes. On 3rd February 1945 the patient was completely blind in both eyes but by the end of February his eyesight was almost normal. Recovery was recorded as complete by the first week of March. Vitamin B₁ 50 to 100 mgm. per day cod liver oil and liver extract had been administered. The author states that to his knowledge this is the first time that optic neuritis has been recorded in association with anti rabies vaccine treatment but the editor of the journal adds a footnote that he is aware of one other case not referred to in the literature in which an optic neuritis was ascribed to the effects of such treatment.

(vi) Miscellaneous

CASALS* in a paper read to the American College of Physicians of New York gave a useful summary of the present state of knowledge with regard to rabies. He covered such points as the incidence of the disease in animals and man in America diagnostic methods prevention and control including vaccination methods. Much of the ground covered has already been referred to in recent reviews of American literature [this *Bulletin* 1943 v 40 200-202 269 653 655-6 1944 v 41 173 179-181 1945 v 42 170]. It is obvious that the author like many of his fellow countrymen considers that the incidence of rabies in the U.S.A. is a blot on their escutcheon. During a period of 15 years the number of cases of rabies in human beings has averaged 55 a year and from 1936-40 there were known to be at least 10 000 cases per annum in animals in the U.S.A. The continued potential danger is much greater than these figures might imply. He stresses the necessity of control of the disease in dogs by application of muzzling orders destruction of stray animals and strict quarantine orders. Such control he states is within the functions of the Public Health officials. [As already pointed out in the reviews on rabies in this *Bulletin* great headway is not likely to be made unless a uniform policy for the control of the disease in the whole of the U.S.A. is adopted this

* KOENIGSFELD E G H Neuroparalytic Accident following Anti Rabies Vaccination. *J Roy Army Med Corps* 1945 Nov v 85 No 5 254-5.
 * CASALS J A Current View of the Rabies Problem. *Ann Intern Med* 1945 July v 23 No 1 74-8.

control to be in the hands of the Bureau of Animal Industry who would have to have the co-operation of the police. The Public Health authorities would take the necessary measures with regard to treatment of human beings. The reviewer understands that this could only be effected by altering the Laws of Congress, but surely this is not an insurmountable difficulty. At present each State has its own policy of control, and in most cases the police apparently believe that responsibility for control lies with public health officials only.] CASALS⁹ states that Australia is kept free of disease by enforcement of quarantine laws. He is not accurate when he says that in England relaxation of the ordinances on muzzling and leashing has been found to result in a sharp increase in the number of cases of rabies, as can be confirmed by reference to the last review on rabies [this *Bulletin* 1945 v 42, 680-682]. [Great Britain like Australia, is favourably placed geographically with regard to control of the disease and the regulations in force require all canines and felines landed in Great Britain from abroad to be quarantined for a period of six calendar months after landing on premises approved by the Ministry of Agriculture. Outside quarantine kennels no cases have been confirmed since 1922, and the disease is likely to be introduced only by criminal evasion of the quarantine regulations. Only when the occurrence of the disease outside kennels was confirmed would muzzling and leashing orders be applied.]

HARVEY¹⁰ in his very comprehensive paper recording the results of well controlled experiments in guinea-pigs, mice and monkeys strongly suggests that further consideration should be given to seroprophylaxis either alone or combined with vaccine in anti-rabies treatment. As he points out, seroprophylaxis in rabies should theoretically be highly effective provided protection is in part or entirely due to circulating antibodies since the time of exposure to infection is known, and the incubation period is often prolonged sufficiently for active immunity to be produced before the virus has established itself in the vital centres in the C.N.S. Yet in the U.S.A. little attention has been given to this method of prevention. The author has reviewed some of the earlier work on anti-rabies serum in which conflicting results were obtained, but the experiments were made on only a few experimental animals and were inadequately controlled. During more recent years from 1934 to 1939 workers notably in Rumania and India [see this *Bulletin* 1934 v 31 642 1935 v 32, 180 610-612 1937 v 34 235 1938 v 35 173 1939 v 36 727] have considered the question of serum prophylaxis in rabies

have carried out experiments in guinea-pigs, rabbits and monkeys to test the effect of anti-rabies serum. These same workers have also reported on the use in man of serum alone and serum combined with vaccine. The present author by applying more recent methods of testing the potencies of virus, antiserum and vaccine has extended these observations and presented the problem in a new light. His main conclusion, which would appear to be well justified, is that his experimental results in animals warrant a trial of immune serum either alone or combined with vaccine in prophylactic treatment of the disease in man. He makes suggestions for the application of serum prophylaxis based on the results of his experiments which differ from anything that has been tried before, (1) Anti rabies serum alone would be administered in those cases of infection now requiring only 14 doses of vaccine i.e. cases of doubtful infection. (2) immune serum followed by commencement of a course of vaccine treatment 6 days later in those cases now requiring 21 doses of vaccine. It is known that a large number of people at present receiving vaccine treatment against rabies have not definitely had an exposure to virus infection and they

⁹ HARVEY, K. Seroprophylaxis in Experimental Rabies. *Pub Health Rep* Wash. 1945 May 18 v 60 No 20 545-60 3 figs. [34 refs.]

are thus exposed to the discomfort and in some cases possible unpleasant sequelae of vaccine treatment. This has been considered necessary as early treatment is indicated and diagnosis of the disease in the biting animal is not always definite. However by employing mice for the diagnosis of the disease in the biting animal it is now possible to get a reliable answer to the diagnostic test in 6 days. If the result is negative no vaccine need be given and the patient would have only had one dose of serum. On the other hand if the result is positive vaccine treatment would be commenced. In the latter case the serum could act in two ways by local destruction of the virus and by retarding the spread of the virus in the C.N.S. as evidenced by the present experiments in which the incubation period was prolonged even although the animals did not prove to be completely protected. This prolongation of the incubation period is probably just what is required for the vaccine to be effective (it would appear that in many failures in vaccine treatment the incubation period is short) hence the better results in the animal experiments with a street strain of virus when serum and vaccine treatment were combined with an appropriate interval of 6 days between the two. The use of serum locally at the site makes possible specific treatment while the virus is localized. The author describes a method for the preparation of an anti rabies serum and concentration of the antibodies and no doubt this could even be improved upon. It would be impossible to discuss all the details of the author's experiments in a short review.

Ian A Galloray

BARANOVSKAYA S. A. [Prolonged Passage of Rabies Street Virus in White Mice.] *Zhurnal Mikrobiologii, Epidemiologii i Immunobiologii* Moscow, 1943 No 12 76-8 [In Russian.]

LEGEZYNSKI [this *Bulletin* 1939 v. 36 725] has stated that street virus and fixed virus behave differently on serial passage in white mice in that the former could only be passed 4-6 times while fixed virus went through 56 passages without loss of virulence and that this difference was sufficiently constant to be used as a means of differentiating between the strains.

In the course of routine passage of various strains of street virus in white mice the author has accumulated data which are in opposition to the findings of Legezynski. Twenty cases of passage from human, dog and bovine brains to white mice are reported: the virus could be taken through 10-30 passages without loss of virulence while the incubation period soon fell to 5-7 days. Only in one case did the virus die out in the fourth passage. It is suggested that the difference between these results and those of Legezynski may be due to the fact that the latter was dealing with less virulent West European strains.

the muscles of his back, and after eight or nine weeks he was able to sit alone. He was given daily hydrotherapy treatment, massages and so on for about two months. His progress has been slow but steady. He can now walk without crutches and can hold light things in his hands. At present he is taking 30 mg of thiamine daily and swimming three or four times a week. In the past month he has been able to take a light job. Perhaps he is one of a group who would have got well eventually regardless of what was done even though he was getting steadily worse until treatment was instituted.

RUSSELL, P F, RAO T R & PUTNAM, P. An Evaluation of various Measures of *Anopheles* Larva Density. *Amer J Hyg* 1945 Nov v 42, No. 3 274-98 8 figs

"Various expressions of *Anopheles* larva density have been computed by simple and by partial correlation technique. The data were collected in a survey covering 33 months, from June 1937 through February 1940 in Pattukottai Town and Taluk Tanjore District, Madras Presidency, India, a recently opened rice field area where *A. culicifacies* is a prolific breeder as well as the malaria vector. The analysis was applied to data pertaining to larvae of this species and to those for all *Anopheles* larvae captured in the area. It has been shown that

"1. Good correlation exists between the logarithms of the monthly captures and either collection unit minutes or square feet. The relationship is, therefore, exponential in character.

"2. When regression equations expressing the relationship between larvae captured and both minutes and square feet are computed, the minutes spent dipping are found to be the determining factor. Area covered does not contribute to the number of larvae captured when time is held constant. Captures in wells during 1937 and in borrow pits throughout the period are exceptions to this rule.

"3. The precise form of the equation describing the relationship differs for larvae captured from different habitats. It also changes from one year to another.

"4. For routine field use a simple ratio of larvae captured to minutes spent dipping furnishes a practicable measure of density."

MOHAN B N Details of the Procedure adopted in maintaining a Laboratory Colony of *A fluviatilis* *J Malaria Inst of India* 1945 June v 6 No 1 75-6

Since January 1944 a colony of *Anopheles fluviatilis* has been maintained at Mettupalaiyam seventeen miles east of Coonoor

It was started from eggs obtained from wild-caught females which were isolated in tubes containing damp filter paper. The eggs were floated in waxed cork rings on water in mud-lined enamel bowls. For larval food hay infusion was added to the water together with brewer's yeast or (when obtainable) a mixture of litmus milk (2 parts) and dehydrated blood serum (1 part). The water was aerated daily. Newly formed pupae were removed to bowls of clean water in a colony cage (2×2×2 feet) which was kept inside a larger one.

Humidity in the cage was maintained by hanging up damp cloths and providing a screened tray of saturated solution of common salt. For the adults glucose water on cotton wool was available and a rabbit with shaven back was put in the cage every night. The bred adults paired only in the presence of a blue light. The females laid their eggs on the water in mud-lined bowls and earthenware pots—more in the pots than in the bowls.

Though the colony now appears to be flourishing it was observed that the females fed more readily on the rabbit after several egg layings. It is therefore important that such a colony should be allowed to become well stocked and established before removing any mosquitoes for experimentation.

H S Leeson

KEENER G G Jr Detailed Observations on the Life History of *Anopheles quadrimaculatus* *J National Malaria Soc Tallahassee Fla* 1945 Sept v 4 No 3 263-70 3 figs

The author worked with a large colony of *Anopheles quadrimaculatus* kept in cages in an institution in Alabama and maintained under nearly constant climatic conditions (high humidity air 76° to 80°F water about 4° lower).

The paper contains a large amount of fact some of it not easy to summarize. Males and females emerge in approximately equal numbers the males before the females—as in many other mosquitoes. The author gives information about the average duration of the early stages including the separate larval instars. The time from laying of egg to emergence of adult is a mean of 21 days and particulars for the duration of the several instars are given. As to the length of life of the female it seems that 50 per cent of them survive 21 days and the maximum is given as 62 days but there are no particulars as to how they were fed whether they were mated and so forth. Pairing takes place most commonly at about 8 p.m. (season and natural illumination not stated) the insects being then extremely active. The female can pair either before or after a blood meal and can then lay several batches of fertile eggs though there is no statement as to whether fertility falls off gradually after a single pairing. The insect takes about 3 cmm. of blood at a meal and during the first few days of life occasionally feeds more than once in the 24 hours. The female deposits eggs while she is standing on the side of the bowl close to the edge of the water the eggs appearing at the tip of the abdomen and being jerked off into the water singly at intervals of a few seconds. Five females

[March, 1948]

were kept singly and averaged over 200 eggs per batch some of them laying nine to twelve batches a figure which does not seem consistent with the statement that the insect may produce three to four thousand eggs.

The paper contains a large amount of valuable information the quantitative material would have been more useful if the author had given original figures rather than percentages and some indication of the consistency of results. All who have maintained colonies of *Anopheles* know that the differences between successive experiments are often great

METCALF R. L. The Physiology of the Salivary Glands of *Anopheles quadrimaculatus* / National Malaria Soc Tallahassee Fla 1945 Sept. v 4 No 3 271-8

The author presents information on the anticoagulins and agglutinins in the salivary glands of *A. quadrimaculatus*.

Anatomically the glands resemble those of other species of *Anopheles* with two lateral acini and one median acinus which is shorter. The lateral and median acini differ in the type of gland cell, and in the pH of the crushed acinus (lateral about 8 median about 7). The ducts including those inside the acini are lined with chitin (identified only by a blue violet fluorescence). The crushed whole gland of the female mosquito contains an agglutinin which is much stronger in the median than the lateral acinus and develops when the insect is a few hours old. It is active even at one in a million, on corpuscles of many sorts of mammal including men of several blood groups but is not active on chicken or turtle blood. The glands of the female also contain an anticoagulin active at dilutions of one in ten thousand. The agglutinin and anticoagulin are thermostable.

Females of other species of *Anopheles* examined by the authors and by other workers contain essentially similar salivary agglutinins and anticoagulins. Females of a number of *Culex* contain neither. Males of *A. quadrimaculatus* contain neither.

The glands of female *A. quadrimaculatus* appear to contain no digestive enzymes protease lipase and amylase could not be demonstrated

P A Buxton

BRADLEY G H & FRITZ R F Observations on Seasonal Occurrence and Abundance of *Anopheles quadrimaculatus* Say / National Malaria Soc Tallahassee Fla. 1945 Sept v 4 No 3 251-62, 12 figs

The authors have tabulated a very large amount of fact on adult *Anopheles quadrimaculatus* in the USA particularly the South and East. They are concerned mainly with the season in which adults occur in catching stations and with their numbers. Data are graphed against average annual temperature and the county is divided into zones at 5°F intervals. In the warm zone (70-75°F) the peninsular Florida southern Texas and Louisiana) adults occur all through the year and this period is longer in the next two isotherms. In the third zone (60-65°F) there is a definite absence of adults from houses during the four winter months and this period is longer in the next two isotherms. The maximum number which may be taken in a catching station is not apparently very different in the five zones. maxima at the peak month run from about 1 000 to 5 000 per catching station. In the colder parts of the country with annual means below 50°F no "significant" numbers of this insect are recorded. [As a rough way of tabulating a large amount of information the method seems to justify itself.]

EYLES D E, SABROSKY C W & RUSSELL J C Long-Range Dispersal of *Anopheles quadrimaculatus* *Pub Health Rep Wash* 1945 Oct 26 v 60, No 43 1265-73 3 figs. (2 on pls.)

The authors have investigated the range of flight of *Anopheles quadrimaculatus* round a certain very large breeding place in South Carolina. Circumstances were unusual and marked mosquitoes were frequently recovered over two miles from the release point the extreme figure was 3.63 miles measured of course in a straight line

The paper is full and well recorded (though the map has no scale) Some 3 500 mosquitoes marked with aluminium powder were released at one point on a single day in the centre of a very large swamp Owing to the extent of the swamp there were no catching stations or domestic animals within two miles. In all 21 of the marked mosquitoes were recovered (in some 40 000 caught and examined) The authors point out that even within one species of mosquito range of flight is influenced by a great variety of factors. They do not regard these observations as contradictory to the generally held view that a one-mile limit of control is generally satisfactory for *A. quadrimaculatus* They conclude that areas must be studied individually. SCHULTES W Bedeutung der Sternalpunktion in Diagnose und Rezidiv prognose der Malaria. [The Value of Sternal Puncture for Diagnosis and Prognosis in Malaria.] *Munch med Woch* 1944 July 28 v 91 Nos 29/30 384-5

Sternal puncture is a valuable means of diagnosis in chronic malaria when parasites cannot be found in the blood or only after repeated examinations by its use the author found trophozoites in 66 (51.5 per cent) of 128 cases of clinical malaria in soldiers. It is also useful for prognosis as regards the likelihood of the occurrence of relapses and for judging the fitness of soldiers for active service after recovering from an attack of malaria. A further 176 patients soldiers, were examined by sternal puncture after a course of atabrin [mepacrine] and plasmoquine [pamaquin] no plasmodia were found in 79 ring forms and dividing forms were present in 7 (they had no fever) half grown and fully-grown parasites were found in 78 and gametocytes only in 12. In these cases no parasites were found in blood films.

The technique is simple and causes little pain but experience is needed in the microscopical examination of the marrow preparations J F Corson

BOOKLESS A S & NAFTALIN J M Typhoid Fever complicated by Benign Tertian Malaria. *Brit Med J* 1945 Dec 8 804-5 1 graph.

The authors have had under their observation recently 34 cases of typhoid fever in two of which benign tertian malaria preceded by 17 days the onset

were 1—
nine
men
T

tr of typhoid and in two where the two infections were present together. The
fir were part of two small outbreaks, and among the first 4 patients P was
r was found in the blood of two, but none received antimalarial treatment [our
table team, in two only "did the temperature charts suggest double
infection showing alternating fevers and remittent fever for the first four
days." In where the fever at the onset was irregularly remittent.

The interest of this paper lies in the patients with concurrent infections of
malaria and typhoid fever. There were, as stated already ten such, and the
course in four was mild, in three "moderate" and in three only was it severe.
There were no fatalities among these and only one patient had a relapse (not
malaria). These figures are to be contrasted with the 24 plain typhoid cases
of which 12 were mild, 8 "moderate" 3 severe and 3 fatal. 8 cases
relapsed. It was noted that antimalarial drugs did not form an obstacle to
positive haemoculture for *Bact. typhosum*. This was positive for 28 out of
the total 44 cases. It is noteworthy also that "O and VI agglutination tests
were not carried out systematically. Thirdly patients with uncomplicated
B.T. malaria always improved on quinine," state the authors. In the early
stages of illness indications of so serious a disease as typhoid fever were absent,
and the early diagnosis on clinical grounds was hindered (the authors term)
by the simultaneous presence of or immediate recovery from malaria.

[It is to be hoped that more of these cases will be reported, and many are
likely to occur. The reviewer noted all the above facts 28 years ago (Ann.
Trop. Med. & Parasit. 1919 v 13 185-214 this Bulletin 1920 v 15 252)]
but they seem to have been forgotten. Sir Patrick MAXSON had noted earlier
still that in malarious subjects the onset of typhoid is often preceded by three
or four paroxysms exactly like those of ordinary ague and that the failure of
response to quinine should put us on our guard. It is—it certainly was—
regrettably far from uncommon for the tropical practitioner to give quinine
to any patient with fever and only when fever continued in spite of the quinine
did he begin to look for causes other than malaria. Again, any disease pneu-
monia for example, in a malarious subject is apt to assume an intermittent
or periodic character. Sometimes, as SCOTT has recorded (*ibid*) the tempera-
ture chart may be that of straight malaria, but clinical signs of typhoid fever
—rose spots, pea-soup stools etc.—may be quite in evidence. The fact that
no fatalities occurred among the authors' patients with the dual infection, and
that 7 of the 10 were mild or moderate corroborates the conclusion in the
referred to above, that cases of coincident enteric fever and malaria
(even though each disease by itself is serious) often run a remarkably mild
course. Incidentally reference may be made to the remark of Sir Almroth
WRIGHT of his having observed that antityphoid inoculation appeared to
reduce the susceptibility to malaria. The subject of the antagonism of diseases
is a very fascinating one and too little work has been done upon it. An inter-
esting thesis, even a whole book, might profitably be written on the question.]

Cape Town. 1945 Sept., v 4, No 7 421-9

PERRET-GENTIL, A. Essais de traitement de la malaria tertiana par la
Vitaquine. [Treatment of Malaria with Vitaquin.] *Praxis*. Berne.
1945 Juh 5 v 34 No 27 402-5 3 charts. [13 refs.]

Vitaquine is a mixture of cinchona alkaloids, 40 per cent. of which are
sulphates of quinine and hydroquinone with a vitamin C preparation, Redoxo
"Roche". Each tablet contains 0.2 gm. of the sulphates of cinchona alkalo-
ids and 0.05 gm. of ascorbic acid. Twenty-five refugees suffering from

relapsing *P. vivax* malaria in Switzerland were treated with this preparation. A course of treatment consisted in the administration of 2 tablets three times a day at meal times for 5 days. After an interval of 3 days the course was repeated. Five or more such courses were given to some patients. Parasites disappeared from the blood on the 3rd or 4th day and the general condition of the patients improved. A certain amount of gastric irritation in some patients was relieved with colloidal aluminum hydrate or belladonna preparations. As the urine of most of these patients originally gave a negative reaction with dichlorophenol indophenol which was rectified by treatment the administration of vitamin C appeared to be beneficial.

Norman White

VOLLNER H & LIEBIG H Nebenwirkungen des Atebrins am Zentralnervensystem. [Side Effects of Atebrin on the Central Nervous System] *Deut med Woch* 1944 July 21 v 70 Nos. 29/30 415-17 [12 refs.]

The author refers to GELLER's conclusions [this *Bulletin* 1945 v 42 9] with which he disagrees and records four cases of benign tertian malaria in which attacks of mania and in one case temporary paralysis were apparently caused by atebrin injected intramuscularly.

The first patient had five attacks of malaria in four months the second third and fourth of which were treated with quinoplasme and no nervous disturbances occurred. In the first attack atebrin was given in doses of 0.3 gm i.m. daily for 3 days and 0.1 gm. orally *t.i.d.* for the next 4 days after the second injection the patient showed mild maniacal excitement and at the end of the oral course he had a severe maniacal attack which began suddenly and lasted for nearly three weeks. In his fifth attack of malaria mild mental disturbance followed the second injection of atebrin.

The second patient also had five attacks of malaria within a few months and all were treated with atebrin and plasmoquine. In the first second and fourth attacks there were no nervous symptoms but in the third attack the third injection of atebrin [presumably 0.3 gm] was followed by the development of cramps numbness and paraesthesia in the legs. His fifth attack of malaria was treated with double doses of atebrin—0.3 gm i.m. *bis die* for two days then 0.6 gm. orally for 5 days. In the night following the fourth injection the patient became acutely maniacal four men being required to restrain him on the following day he had hiccup laryngeal paralysis and flaccid paralysis of the legs with diminished deep reflexes. He recovered quickly from the mania but the paralysis lasted for about ten days.

The third patient was treated for his first attack of malaria with double doses of atebrin—0.3 gm i.m. *bis die* for three days. In the night following the third day he got out of bed ran across a yard barefooted to the office and demanded to be shot dead immediately a few minutes later he became violently delirious requiring eight men to hold him. No other neurological symptoms developed.

The fourth patient had three attacks of malaria in three months. The first two attacks were treated with atebrin 0.3 gm i.m. daily for three days then 0.1 gm orally *t.i.d.* for 4 days and no nervous symptoms developed. His third attack was treated with double doses—0.3 gm i.m. *bis die* for two days. In the next night but one after the last injection he wandered aimlessly about the hospital. Treatment with atebrin 0.6 gm. daily by mouth was continued Luminal [phenobarbitone] being also given and there were no further mental disturbances.

The authors add that such attacks are rare the first patient was one among 350 treated with the usual daily dose of 0.3 gm of atebrin but the other three were among over 100 patients treated with double daily doses. Treatment

was not interrupted but was continued by oral administration and the authors think that their results justify this decision. [See also this *Bulletin* 1945 v 42, 253-343 and 695] J. F. Corson

ZELIGS M. A. The Management of Chronic Malaria between Attacks, with special reference to the Effect of Nicotinic Acid on Malarial Headache. *J Amer Med Ass* 1945 Nov 17 v 129 No 12, 796-8.

Many members of the fighting services contracted malaria while in actual combat against the enemy. Chills and fever were an accompaniment of battle weariness, hunger, intense fear and exposure to wet and cold. After removal of such patients from the field, the febrile attacks could be readily cured, but symptoms such as easy fatigability, irritability, loss of weight, headache, backache and disturbed sleep were liable to persist. This condition was often described as post-malarial asthenia. The description is not apt. Malaria may play a part in the causation of the condition but so do the physical and psychological stresses of combat, and possibly also other tropical infections such as amoebiasis and ankylostomiasis. After return to the United States and three months of reconditioning, malaria infections may persist but "asthenia" is very rare. The term "post-malarial asthenia" should be abandoned.

There are however certain symptoms so constantly associated with chronic malaria as to incriminate the malaria parasite as the cause. Most common of these is malarial headache. This headache is usually bifrontal, mild to moderate in severity, never hemispherical, has no neurological prodromes, occurs on rising in the morning and usually improves after the patient has been up for a few hours. Prolonged persistence of malarial headache may produce secondary "neurotic-like" phenomena. The sufferers are not relieved by the usual headache remedies. Twenty-five selected patients were treated with nicotinic acid, 100 mgm. by mouth. The headache was relieved in 10 cases, there was moderate improvement in seven cases and no improvement in eight. No parasites were found in the blood and there is no record of antimalarial treatment. Norman White

RUPPOL, A. Paludisme, enfance noire et quinisation au Cercle de Gombo-Matadi en 1938-1939 [Malaria, Native Children and Quinization in the Gombo-Matadi Region of the Belgian Congo in 1938-1939.] *Rec Trav. Sci. Méd. Congo Belge* 1945 July No. 4, 82-9.

In 1938 the author examined thick smear blood preparations taken from a number of children in three villages that had previously been outside the range of activity of any medical organization. The children were considered in the villages to be enjoying normal states of health, though a child without an enlarged spleen was very exceptional. In 1939 infant welfare centres were at work and infants were given prophylactic quinine 0.25 gm. four times a week. In that year the blood of all infants who were ill and who needed medical treatment was examined. The results of the blood examinations in the two years are given in detail and compared. In 1938 the blood of 16 out of 17 infants below the age of 6 months and of all older children up to 5 years, contained malaria parasites. *P. vivax* was rare. *P. falciparum* and *P. malariae* were both abundant. The *P. falciparum* gametocyte index of these infants up to 5 years was 52 per cent., the *P. malariae* gametocyte index 54 per cent., the *P. vivax* gametocyte index 4 per cent. Mixed infections were common. In 1939 the parasite index was but little reduced, but the parasite density was markedly less. The gametocyte index was 50 per cent., lower mixed

infections were rare and quartan infections were much fewer except during the first six months of life. These improvements are attributed to the distribution of prophylactic quinine

PHILIP M I RAMAKRISHNA V & RAO V V Turmeric and Vegetable Oils as Repellents against Anopheline Mosquitoes. *Indian Med Gaz* 1945 July 1 80 No 7 343-4

The authors have observed that in the Joypore hill tracts and on the Madras coast spleen rates in boys are much higher than in girls. They think that this must be due to girls being less bitten by *Anopheles* than boys and therefore less infected with malaria. This in turn is attributed to the fact that girls and women apply turmeric and vegetable oils to their bodies daily. In cage experiments an application of turmeric and mustard oil subsequently washed with water but without soap is repellent to hungry *Anopheles* of several species.

[It is one thing to repel in a cage experiment quite another to find something which will remain even moderately repellent after rubbing on garments and for several hours]

Summary prepared by LAMBERT J D Major R.E.] 3 mimeographed pp 2 figs. [Dated 23rd November 1944]

These papers constitute between them a lengthy report on the early trials with DDT in the Far Eastern theatre of war to test its value in the control of mosquitoes both adult and larval for the protection of troops against malaria. All the trials were of the field type. For destruction of adult mosquitoes a 5 per cent. solution of DDT was applied usually by means of a power driven sprayer of the paint spray type the average dose of DDT per square foot of wall surface was 56 mgm the huts treated were both thatch and of permanent construction and the mosquitoes concerned were *Anopheles subpictus* *A. annularis* *A. hyrcanus* *A. culicifacies* and *A. pallidus*. The normal procedure was to select a suitable group of houses and to establish catching stations in them in which periodical mosquito counts were made all dwellings were then sprayed the catching stations being reserved to the last and counts were continued in the treated catching stations.

Catching stations were of two types—netted and un netted. The former were completely open at night but were closed by an arrangement of mosquito netting at dawn thus imprisoning any mosquitoes in them they remained closed for some hours until the count was made. It was intended by this means to avoid errors due to the early morning migration of mosquitoes though it was recognized that the method held them artificially in contact with treated surfaces from which they might otherwise have been repelled. The un netted stations were ordinary open houses in which hand collections

were made some hours after dawn. Curiously and for reasons not understood, the catches in the two types of stations were the reverse of what had been expected, being higher in the un-netted stations, from which the mosquitoes had an opportunity of escape than from the netted ones.

An almost complete disappearance of mosquitoes was recorded during the month after DDT treatment after which there was a steady increase in anophelines in un-netted stations though the numbers previously found were not reached for several months. The results were better when every habitation within the area was treated. DDT exerted no repellent effect, but there was some inhibition of biting in rooms which had recently been treated, and it was found that *Culex fatigans* was more resistant than *A. subpictus*.

The various types of equipment which might be used for distribution of residual films were surveyed, and it was concluded that the "Kent" pattern (a pneumatic knapsack machine in the body of which a high pressure is initially obtained by means of a hand pump) was suitable, though it needed some modification. The technique of application is described.

Larval mosquito control was carried out from the air using Hurricane aircraft equipped with two tanks, each holding 250 pounds of 5 per cent. solution of DDT in kerosene and application was at the rate of two to three quarts per acre. Some of the applications were made from formation flights of several aircraft in line abreast. Complete immediate control of swamp-breeding anophelines (*A. hyrcanus* and *A. philippinensis*) was secured. Fully developed larvae did not re-appear for about 12 days after treatment and this result was associated with a marked reduction in the adult mosquito prevalence in the neighbourhood. When the same method was applied to country in which streams, containing larvae of such species as *A. minimus* abounded, full destruction of larvae was not secured, owing to the shielding effect of overhanging vegetation. Nevertheless, the DDT remaining on this vegetation killed mosquitoes coming to lay or newly hatched, and in consequence very effective control of adults was secured despite the incomplete larvicidal result.

ARMISTEAD, M. H. & ARTHUR, J. H. Future Military Malaria Control. *Southern African Med J* 1945 Oct 13 v. 19 No. 19 361-5 2 charts & 1 map.

The title of this paper "future military malaria control," is not really applicable to the subject matter which consists of an account of the incidence of malaria and the measures taken for its control on the Indo-Burma front during the years 1942 to 1944. Very high malaria rates were experienced in the first part of the campaign, though even then the control measures adopted were instrumental in avoiding a complete breakdown such as occurred in some areas where they were neglected. The anophelines incriminated as carriers were *Anopheles minimus*, *A. parvipes* var. *caudatus*, *A. leucophrys*, *A. sinensis* and *A. philippinensis* one or more of which occurred in considerable numbers in most areas and almost throughout the year. The seasonal prevalence of each is shown in a useful histogram.

Drainage was considered to be the backbone of control though adult destruction and larvicides were also used. But despite these and a carefully organized system which covered the whole line of communications the incidence of malaria remained high, the chief incidence being among forward troops, to whom suppressive treatment had been given from the first. Failures in control among these troops were due to neglect to take mepacrine when on patrol when they were away from the supervised parades at which it was administered, to reluctance to use head nets which obstructed vision, and to dislike for and inefficiency of the original repellent cream, or even the later pyrethrum

creams and dimethyl phthallate. These last objections were finally overcome by the adoption of a $\frac{1}{4}$ in. mesh net which when impregnated with dimethyl phthallate afforded complete protection against mosquito bites for 72 hours while following the Australian demonstration of the efficacy of mepacrine an educational campaign resulted in the growth of greater faith in it and its more regular use.

Also in the later part of the campaign DDT became available and this was particularly valuable when applied from the air for the control of breeding places made difficult of access by jungle or by enemy mines.

The authors consider that the introduction of DDT and the use of mepacrine and repellent fish nets stand out pre-eminently as advances in malaria control which they will profoundly influence in the future.

LOZANO MORALES A Problemas prácticos de lucha antipalúdica. Estudio experimental de un nuevo larvicida [Practical Antimalarial Problems Experimental Study of a New Larvicide.] *Rev Sanidad e Hig Pública* 1945 June v 19 No 6 413-24

Exadoruro de benceno [benzene hexachloride or hexachlorocyclohexane $C_6H_6Cl_6$] is a white powdery substance insoluble in water. It was synthesized in England as long ago as 1820 but only recently have its insecticidal properties been recognized. The author has demonstrated its value as a larvicide. Laboratory and field experiments are described. Excellent results were obtained by the application of the powder 1 per cent mixed with road dust to *Anopheles* breeding places. Suspensions in water following Barber's method of distributing Paris green also gave good results. Norman White

HENDERSON J M Antimalaria Measures for the Protection of Military Personnel in Puerto Rico and their Applicability to Civilian Malaria Control. *Puerto Rico J Pub Health & Trop Med* 1945 June v 20 No 4 419-45 6 charts & 1 fig [Spanish version 446-72.]

COULSTON I CANTRELL, W & HUFF C G The Distribution and Localization of Sporozoites and Pre-Erythrocyte Stages in Infections with *Plasmodium gallinaceum*. *J Infect Dis* 1945 May-June v 76 No 3 226-38 [14 refs.]

In a previous paper [this *Bulletin* 1945 v 42 538] two of the authors described the development of sporozoites of *P. gallinaceum* in the skin and organs of chickens following cutaneous and intravenous inoculations. In the present paper are recorded the results of the inoculation into uninfected birds of blood and of organ or tissue emulsions of infected birds at varying intervals after the latter had received an injection by mosquito bite or by syringe of sporozoites. In chickens bitten by infected *Aedes aegypti* none of the organs or the blood were infective during the first 36 hours. The muscles at the site of the bite were, however infective. From the 36th to the 79th hours occasional infections were produced by the blood and some organs (lung spleen heart). After the 79th hour the blood and organs regularly produced infections. After intravenous injection of large numbers of sporozoites the lungs spleen kidneys liver pancreas and muscle produced infections during the first 36 hours. The blood was infective at the 36th hour but was negative thereafter till the 82nd hour. At the 70th hour all tissues became infective. When suspensions of sporozoites from 130-200 mosquitoes were inoculated intravenously the presence of sporozoites in the blood was demonstrated for 5 to 20 minutes by subinoculation and up to 15 minutes microscopically.

Subsequently the blood was negative till 40 hours later. Infected mosquitoes were allowed to bite the tip of a chicken's wing. The tip was isolated by ligature after varying intervals and then removed. Even when only 45 seconds had elapsed before the ligature was applied, the birds became infected. In practically all cases the removed portion of wing produced infection when subinoculated to uninfected chickens. The result indicates that dispersal of sporozoites probably takes place by way of the blood stream. [These results may be compared with those observed in man by FAIRLEY and his colleagues see this *Bulletin* 1945 v 42, 630.] C. M. Wenyon

JACOBS H. R. Immunization against Malaria. Unsuccessful Attempts to Increase Resistance of Ducklings to *Plasmodium lophurae* Infections by previous Injections of Materials containing the Forssman Antigen. *Amer J Trop Med* 1945 Mar v 25 No 2, 151-3.

In a survey of animals susceptible to malaria it was noted that those possessing Forssman antigen or hapten are generally not liable to malaria infection. In most animals the hapten when present occurs in the tissues but in the sheep and goat it is present only in the erythrocytes, while in the chicken it occurs both in the tissues and the erythrocytes. It is noteworthy that the chicken is a striking exception to the rule of non-infectivity. An attempt was made to increase the resistance of ducklings to *Plasmodium lophurae* infection by administering, at intervals of a few days subcutaneous injections of the hapten prepared from guinea-pig kidneys, horse kidneys and sheep erythrocytes. These were employed as fresh suspensions or extracts of various kinds, heated or unheated. In only one of the experiments, in which heated suspension of guinea-pig kidney was used did there appear to be any protection. It was not possible however to obtain a like result when the experiment was repeated. The conclusion is that attempts designed to increase the resistance of ducklings to the infection have yielded largely negative results. C. M. Wenyon

BLACKWATER FEVER.

BRICKMANN G & WERTHEIMER, E. Lysis of Red Blood Cells by Tissue Slices. *Brit J Exper Path* 1945 Aug v 26 No. 4 217-24. [11 refs.]

This is an account of an attempt to reproduce the findings of MACGRAITH *et al.* (this *Bulletin* 1943 v 40 584) in regard to lysis of red blood corpuscles in the presence of tissue slices. The authors confirm that washed tissue slices haemolyse washed red cells. They find that such lysis is inhibited by heat but not by serum, potassium cyanide or mercuric chloride and that pre-incubation of the tissues "shortens the induction period and results in more rapid lysis." The lytic power of tissue slices is not species-specific. The authors conclude that the lytic phenomenon depends on autolysis and stasis and is "not connected with normal or pathological blood destruction."

[PONDER (*J Gen Physiol* 1944 v 27 483) states that he had no difficulty in confirming the results of Macgrath *et al.* so far as the lytic effect of tissue slices was concerned. He found that the lytic agent was destroyed by heat, and by high and low pH. He agrees with the present authors that the lytic agent is not species-specific. Ponder considered that the tissue lytic agent was possibly similar to lyso-lectin. The present authors disagree with this. The disagreement that exists concerning properties of tissue lytic agents is probably due, fundamentally to the fact that there is, as yet, no well standardized biological technique for their investigation.] B. G. Margrafs.

TRYPANOSOMIASIS

WEINMAN D & FRANZ K. Early Results of the Treatment of African Trypanosomiasis with Two New Arsenical Preparations (Melarsen Oxide and 70A) Preliminary Report *Amer J Trop Med* 1945 July v 25 No 4 343-4

Two new arsenicals were tested against sleeping sickness in Liberia —(i) Melarsen oxide (supplied by Parke Davis and Company) a trivalent arsenic oxide derived from the pentavalent Melarsen previously introduced into therapy by E. A. H. FRIEDLICH [literature references not cited by the authors see this *Bulletin* 1941 v 38 634 and *J Amer Chem Soc* 1944 v 66 1775] and (ii) a substance designated as 70A (supplied by Dr Harry EAGLE) the composition of which is undisclosed beyond the statement that it is a phenyl arsenoxide [Cf EAGLE *et al* this *Bulletin* 1945 v 42 15 EAGLE *ibid* 354]

(i) *Melarsen oxide*

Oral treatment 12 patients 8 of whom showed evidence of neurological involvement (5 with trypanosomes in the cerebrospinal fluid) were treated with 3 mgm. per kgm. daily for 5 to 8 days. The blood lymph glands and cerebrospinal fluids were clear of trypanosomes by the end of the course or in some late cases after a second course. The cerebrospinal fluid cell counts of the late cases fell after treatment in all instances though one of these patients was subsequently judged to have relapsed because four months after his second course the count was found to be higher than when examined the previous month.

Intravenous treatment 8 patients 3 with neurological involvement were treated by 0.1 mgm./kgm. daily for 7 days. Results in early cases were similar to those obtained by oral treatment. However 2 of the 3 late cases failed to respond. Nevertheless the authors write that for maximal effect the parenteral route is preferable to the oral [this is not borne out by the data which they present]

(ii) 70A

This compound was tried in 10 patients and the authors conclude that it was effective in the early stage but neither prevented nor ameliorated cerebral involvement. [It seems rather odd to credit a compound with effectiveness against the early stage of a disease whilst also charging it with inability to stem the progress of that disease.]

[The observation periods after treatment by Melarsen oxide apparently varied from 2 to about 4 months and this is quite insufficient for proper substantiation of the authors' claim as to the indisputable efficacy of Melarsen oxide in meningo-encephalitic cases. Their criteria of efficacy in cases of neurological involvement are inadequate as for example in the significance which they attach to the fact that in eight such cases the cerebrospinal fluid cell counts initially ranging from 65 to over 1,200 with an average of 357 cells per cmm declined after treatment to a range of 7-556 with an average of 138. To give point to this criticism the reviewer has applied Weinman and Franz's method of evaluating cerebrospinal fluid cell count changes to the data provided by HARDING in Table I (p. 107) of his paper on the effects of antypol trypanamide and diamidines [this *Bulletin* 1946 v 43 105]. In seven cases treated by pentamidine or propamidine in which the initial cell counts were as in Weinman and Franz's late cases above 65 per cmm the counts in all individual cases were, as in Weinman and Franz's experience, reduced after treatment (4 to 6 months later) and the range of 74-538 with an average of 255 fell to a range of 3-17 with an average of 10 cells per cmm.]

According to Wemman and Franz therefore pentamidine or propamidine would be judged highly efficacious in meningo-encephalitic cases which in fact they are not.

With regard to 70A, it is disappointing to find in a highly respected scientific journal that space is allowed for a description of the unpromising results of therapeutic trials with a compound whose formula is not revealed.]

LEWILLON R. Le piégeage expérimental de *Glossina palpalis* à la Mission Médicale du Kwango. [Experimental Trapping of *Glossina palpalis* at the Kwango Medical Mission.] *Rev. Travaux Sci. Mid Congo Belge* 1945 July No. 4 45-57 2 figs.

Tsetse flies breed so slowly that they can sometimes be almost exterminated by measures aimed at destroying the adult flies. The Harris trap was markedly successful against *Glossina pallidipes* in Zululand, but gave disappointing results elsewhere, especially against *G. palpalis*. Two traps devised by SWYNNERTON one using a flat shaded screen as an attractant and the other containing an animal (bullock or pig) have had a limited success in Tanganyika and elsewhere.

An easily and cheaply constructed trap made entirely from indigenous materials, and resembling in outline a man, is described here. The lower part is similar to the "crinoline" trap and the insects enter this from beneath. They then fly upwards to the light and find themselves trapped inside a hollow gourd pierced with numerous small holes to let in the light—the gourd represents the head.

When carefully sited in a heavily infested fly belt this new mannequin trap caught many flies and subsequently reduced the density. It was much more successful than the Harris trap and as good or better than the Swynnerton models—it was also the easiest and cheapest to construct.

As an anti-sleeping-sickness measure, trapping is compared with prophylactic injections of Antypol (four injections per annum). It is more expensive to treat one individual than to construct four traps. The author considers that trapping is often the more practical measure.

Kenneth Mellanby

MAZZA, S. MIYARA, S. & JORG M E. Investigaciones sobre enfermedad de Chagas. Naturaleza de la reacción conjuntival en primer período de la enfermedad de Chagas. Enfermos comprobados exclusivamente por demostración de leishmanias de *S. cruzi* en biopsias conjuntivales. [Studies on Chagas's Disease. The Conjunctival Reaction in the Early Period. Leishmanial Forms of *T. cruzi* in the Conjunctiva.] *Universidad Buenos Aires. Misión de Estudios de Patología Regional Argentina (Jujuy)*. Publicación No 69 1945 152 pp. 163 figs.

In an article published in 1944 the authors gave an account of the histopathology of the conjunctiva in the early stage of Chagas's disease [this *Bulletin* 1945 v 42, 792]. The present work is a sequel and an amplification of the former. The authors start by describing the projection microscope they use for examining biopsy specimens of the conjunctiva—the Zeiss Ultraphot and refer to the Fuess Orthophot and the Ernst Busch Citophot. It is an adaptation of the trichinoscope to a microscope. The apparatus is depicted and the optical projection presented diagrammatically.

They then pass on to give very detailed descriptions of the histological changes in portions of the conjunctiva taken by biopsy from 20 patients. The ages of the patients varied from 5 to 63 years. In 8 of these the diagnosis

was in no doubt in 7 trypanosomes were found in the blood and in the other xenodiagnosis was positive in 5 others the Guerrero-Machado test was positive but not the blood examination nor xenodiagnosis in the remaining 7 none of these was positive and the diagnosis rested on the clinical history the general appearance and the histology of the sections made from the biopsy specimens

With a view apparently of driving home their point the authors indulge in a good deal of repetition. A record of the details of one case may be reproduced here to acquaint the reader with the histological changes present

From a man of 43 years on the sixth day after he had been bitten on the right eyelid by an infective bug a fragment of the conjunctiva was taken for section and examination. The changes are thus described. Marked alteration in the conjunctival structure due in part to inflammatory infiltration and in part to epithelial erosion. There is intense congestion with haemorrhages some localized others more diffuse and serofibrinous oedema. There is moderate perithelial infiltration with small dense collars of perivascular infiltration constituting in places nodular masses with fibroblastic proliferation and oedema. There is no leucocytic invasion but atrophy with erosion and ulceration and the vessels are intensely congested to form a sort of telangiectatic granuloma. In the parts less acutely affected the nodules are smaller but the same epithelial atrophy is seen. Cytologically the usual types of cell associated with inflammatory processes are present together with proliferation of histiocytes and some fibroblastosis mingled with myeloid infiltration and serofibrinous exudation. Among hyperplastic histiocytes there is a dense fibrin reticulum and thin connective tissue fibrils of the inflammatory new growth type. Certain parts showing the nodule formation show also multinucleate structures tending to a coagulative necrobiosis of the central connective tissue in the interior of which are free leishmanial forms of *T. cruzi*. *Leishmania* are commonly present in the macrophages and a few were seen in the walls of the capillaries. (The whole work is embellished with photographs of the patients depicting the palpebral oedema and with photomicrographs of the tissue changes beautifully reproduced.)

LEISHMANIASIS

DA CUNHA, A. M. Infecções experimentais na Leishmaniose tegumentar americana. [Experimental Mucocutaneous Leishmaniasis] *Mem. Inst. Oswaldo Cruz* 1944 Oct v. 41 No 2 263-82 26 figs on 7 pls. English summary

Working with recently isolated cultures of *Leishmania brasiliensis* the author inoculated rhesus monkeys intradermally over the superciliary arches or on the nose. The course of the infection varied according to the type of lesion produced. Usually only a local lesion developed, in one to two months which healed in three to eight months. In some cases however involvement of the nasal mucosa occurred. When this happened it was not the result of direct extension from a cutaneous lesion which may occur as has previously been reported, but was due to the spread of the infection to the mucosa by some other channel. The nasal lesions which were in the form of nodules on the nasal septum and polypi which completely shut off the naso-pharynx showed no tendency to spread to the pharyngeal region. Though the cutaneous lesions healed those of the nasal mucosa persisted. Dogs were also successfully inoculated in the skin of the nose. One agouti (*Dasyprocta agouti*) and

According to Weimann and Franz, therefore pentamidine or propamidine would be judged highly efficacious in meningo-encephalitic cases, which in fact they are not.

With regard to 70A, it is disappointing to find, in a highly respected scientific journal, that space is allowed for a description of the unpromising results of therapeutic trials with a compound whose formula is not revealed.]

FEVERS OF THE TYPHUS GROUP

VARLEY Florence M & WEDDOW F R. Application of a Quantitative Complement Fixation Test to the Serum Diagnosis of Typhus Fever. *J Immunology* 1945 Sept v 51 No 3 139-46 [14 refs.]

The authors describe the highly specialized technique employed in a new quantitative method of carrying out the complement fixation test in the diagnosis of typhus fever. The method was devised by WADSWORTH, MALTNER and MALTNER in 1938 and is described by Wadsworth in his book *Standard Methods of the Division of Laboratories and Research of the New York State Department of Health*, 1939 Williams and Wilkins Co. Baltimore.

In the method the end point adopted is described as follows: 50 per cent. haemolysis of the cells present as a standard of reference rather than the point of complete haemolysis. This renders evaluation of the results much more precise and satisfactory. A set of four charts for use in carrying out the test is reproduced. Preliminary trials are said to show that lytic or slightly anticomplementary properties of the normal serum used for diluting the anti-serum under test do not influence the quantitative estimation of the amount of complement rendered inactive by the antigen-antibody mixture.

The new technique is not likely to appeal to workers other than those who have exceptionally complete laboratory facilities at their disposal.

SCHÄFER, K. H. Stoffwechseluntersuchungen an Fleckfieberkranken. [Investigations into the Chemical Changes in Typhus Patients.] *Deut med. Woch.* 1944 July 21 v 70 Nos. 29/30 417-19 2 figs. [20 refs.]

The author has studied the chemical composition of the blood and urine of several patients during severe attacks of typhus fever.

The pronounced fall in the chloride content of the urine during the acute stage of the fever was not accompanied by any evidence of chloride retention.

in the blood there was instead an appreciable diminution in six of the eight cases investigated. In five of these six cases the serum sodium range was 184-216 mgm. per cent and the chlorine range was 284-334 mgm. per cent. No pronounced fall was observed in the serum calcium which ranged between 8.2 and 10.0 mgm per cent. The potassium content of the serum was considerably increased especially in very severe attacks in which the findings ranged between 23.4 and 74.5 mgm per cent. The residual [non protein] The serum proteins were rather low in all the cases investigated during the second week they were 4.88-7.6 gm per cent. The residual [non protein] nitrogen was not greatly increased it was only 21 mgm. per cent in a fatal case and in the other four very severe cases it was 45-63 mgm per cent during the second week. The author concludes that great increases up to 100 mgm per cent or more occur only in cases complicated by glomerulonephritis which was common during some epidemics in extremely cold weather. The findings especially in connexion with the chlorides suggested changes in the permeability of the capillary walls associated with a diminution in the volume of the blood plasma and a resultant fall in the blood pressure. The condition is described as one of transmineralization. *John W D Megaw*

DUENSING F Über pathologische Fremdreflexe bei Fleckfieber Encephaliden von choreatisch myoklonischem Gepräge [Unusual Pathological Reflexes of Choreiform-Myoclonic Type in the Encephalitis of Typhus Fever] *Der Nervenarzt* 1944 Mar-June v 17 Nos 3/6 73-80 [10 refs]

Two cases are described in detail in which the patients suffered from a choreiform myoclonic syndrome after attacks of typhus fever. The abnormal reflexes were of a type that the authors had never seen except in athetosis myoclonus and occasionally in Parkinsonism after encephalitis. The condition persisted for at least 14 months and though there was some improvement by the end of that time it seemed unlikely that complete recovery would ever happen. *John W D Megaw*

GÄRTNER W Erkrankung von Tonussteuerungszentren bei Fleckfieber [Affection of the Tonus-Controlling Centres in Typhus Fever] *Der Nervenarzt* 1944 Mar-June v 17 Nos 3/6 80-86

The author describes and discusses at length a peculiar case of mental disorder which began 17 days after defervescence from a severe attack of typhus fever. The symptoms were varied and at different times suggested schizophrenia, hysteria and hypnosis. The main drift of the author's argument is that the manifestations resulted from damage to the nerve centres of the mesencephalon which control various mental chemical and mechanical functions of the body.

The patient was observed for four months and although he had made a complete physical recovery his mental condition was still far from normal. The author stresses the need for an investigation by a psychiatrist in all cases in which a soldier commits offences against discipline after having suffered from typhus fever. *John W D Megaw*

RAETIG H Die fraktionierte Rekonvaleszenzserumbehandlung des Fleckfiebers [The Treatment of Typhus Fever with Fractional Doses of Convalescent Serum.] *Med Ztschr* 1944 Nov v 1 No 2 59-60

Having had unsatisfactory results from single large doses of convalescent serum the author decided to try small doses given daily by the intravenous

route. The treatment was started as early as possible and was continued till defervescence. At first the doses were 20-40 cc. but later they were increased to 40-60 cc. and better results were obtained with the larger doses especially in severe attacks.

In a large number of cases treated in this way the case fatality rate was 7.5 per cent as compared with a rate of 18.3 per cent among control patients. Although alternate controls were not employed the author insists that patients in whom the onset was specially severe were selected for the treatment and that the number treated (more than 300) was so large that the element of chance was eliminated.

JOHN W D MEGAW

LE GAC P Un cas mortel de typhus tropical constaté en Haute-Côte-d'Ivoire.
[A Fatal Case of Tropical Typhus in the Upper Ivory Coast.] *Méd Trop*
Marseille. 1942 June v 2 No. 6 473-7

The clinical features of a sporadic case of typhus-like fever are described the patient died on the 12th day.

The Weil-Felix reaction was tested on the 10th day. *Proteus* O1A was feebly agglutinated at a titre of 1-50 the O119 and O12 strains were not agglutinated. A Patas monkey and two rabbits were inoculated with the patient's blood, each animal received 5 cc. by the intraperitoneal and 1.0 cc. by the intraocular route. Endocyclitis was caused in the monkey and in one rabbit which also had a febrile reaction, but injections of its brain substance caused no reaction in a monkey two rabbits and two white rats. In the Weil-Felix responses in the originally inoculated animals, the highest titres were 1-60 in one rabbit against O119 and 1-100 in the monkey against O1A.

The author regarded boutonneuse and tick fever as being excluded because the patient had neither the very characteristic massive eruption nor the O12 reaction observed in these fevers. He concluded that the disease was "related to Malayan typhus or the jungle typhus of Bengal."

[The evidence in support of a diagnosis of mite-borne typhus and against that of tick borne typhus does not appear to be convincing but judgment can be reserved because the author states that 16 other cases from different parts of the Upper Ivory Coast are being studied.]

TOPPING N H. Tsutsugamushi Disease (Scrub Typhus). The Effects of an Immune Rabbit Serum in Experimentally Infected Mice. *Pub Health Rep* Wash. 1945 Oct 12 v 60 No. 41 1215-20

Serum of rabbits immunized by rickettsiae of tsutsugamushi disease was found capable of preventing the death of mice infected by lethal doses of homologous strains of rickettsiae. The serum was injected subcutaneously and was effective in some cases, even when given up to 72-168 hours after the time of infection. Serum of one of the four rabbits used was relatively ineffective. Large doses were more effective than small.

The rabbits were immunized by intravenous injections of infected yolk-sac material given on two consecutive days weekly for three weeks, and the serum was collected 19 days after the last injection.

The antibody content of the serum was increased by a further series of injections given after a resting period of several weeks.

Tsutsugamushi disease is regarded as specially favourable for serum treatment because of the possibility of immediate diagnosis at the time of onset in many cases owing to the presence of the eschar.

The author mentions that he has already found penicillin ineffective in the treatment of infected white mice and that ANDREWS, KING and VAN DEN

ENDE have had similar negative results with para sulphonamido-benzamidoxime hydrochloride. [For the results of this drug in experimental typhus see this *Bulletin* 1945 v 42 20] *John W D Megaw*

YELLOW FEVER.

DÍAZ I Brote de fiebre amarilla selvática en Venezuela durante el año 1944 [Outbreak of Jungle Yellow Fever in a Venezuelan Area in 1944] *Boletín Oficina Sanitaria Panamericana* 1945 July v 24 No 7 589-96 1 map English summary

An outbreak of jungle yellow fever occurred in an area close to the Andean range in the States of Barinas, Bolívar and Táchira in Western Venezuela, near the Colombian border. First suspicions of the presence of the disease were aroused by the examination of a viscerotomy specimen from a patient from Cuíte who died on July 22 at the Hospital Vargas of the city of San Cristóbal in the State of Barinas. It was also found out that in the section of San Cristóbal-La Colorada highway several fatal febrile cases with blood vomiting had occurred about the same time. The chief of the Yellow Fever Division of the National Department of Health proceeded on September 3, 1944 to the area in question with a laboratory worker and an entomologist. A total of 12 cases of yellow fever, all of the jungle type, were verified by viscerotomy in areas completely separated in the three States involved. Two of the cases were in the State of Barinas, located in an oil camp in a jungle zone between the Andean range and the Barinas plain. In the State of Táchira nine fatal cases were verified and 21 other cases were studied clinically and epidemiologically, which were confirmed as yellow fever by the mouse protection test performed in the surviving patients. In the State of Bolívar so far considered the only endemic yellow fever zone in Venezuela, only one case was found in a jungle area near San Félix on the Orinoco river. It is supposed that in the whole area affected there must have been about 120 cases with a 70 per cent death rate. (The last two patients reported were from La Tigra, about 16 miles S.W. of Barinas and died in the Barinas hospital on November 29 and December 6 respectively.) Precautionary measures were immediately taken through the local Health Authorities including a campaign against *Aedes aegypti* in urban districts, temperature-taking of all travelers, checking by the health authorities of febrile cases admitted to hospitals and general vaccination against yellow fever. By the end of the year 28,263 vaccinations had been made as follows: State of Apure 3,162; Barinas 5,000; Táchira, 17,342; Zulia 1,357; Bolívar 1,402. In the State of Bolívar 14,000 persons had already been vaccinated during the two previous years. This represents about 50 per cent of the total population and leaves unprotected only the Indians deep in the jungle.

WADDELL, Mary B. Persistence of Yellow Fever Virus in Mosquitoes after Death of the Insect. *Amer J Trop Med* 1943 July v 25 No 4, 329-32.

Aedes aegypti were fed on marmosets or Cebus monkeys infected with jungle strains of yellow fever and subsequently tested for virus content by intra cerebral inoculation into white mice.

The mosquitoes were then killed either by chloroform, ether potassium cyanide or tobacco smoke and after varying time intervals groups of five were tested for virus content.

It was found that after death of the mosquito from chloroform, most of the virus activity was lost in 30 minutes and was completely absent after 1 hour. On the other hand significant amounts of yellow fever virus were recovered from the bodies of mosquitoes killed by the other three methods two hours after being killed, and were still present up to 45½ hours in those killed by potassium cyanide. Virus was also recovered from *Aedes aegypti* that had died of starvation up to 25 to 41 hours after death.

Specimens of *Haemagogus equinus* and *H. spegazzinii* which had died spontaneously after feeding on infected monkeys, were collected at intervals of from 1 to 3 days and tested for the presence of virus. It was recovered from mosquitoes collected within 24-48 and 72 hours after death, the exact time of death being unknown.

The use of ether is recommended as the most satisfactory method of killing insects when it is intended to use them in attempts to isolate yellow fever virus.

SMITHBURN K. C. Experimental Studies on the Yellow Fever Protection Test. *J Immunology* 1945 Sept. v 51 No 3 173-89 [10 refs.]

In 1930 THEILER [*this Bulletin* 1930 v 27 872] discovered that white mice were susceptible to yellow fever virus. This led to the development of the intracerebral neutralization test of Theiler [*ibid* 1933 v 30 714] and to the intraperitoneal test of SAWYER and LLOYD [*ibid* 1932, v 29 198]. The latter was the simplest method for estimating protective antibodies in human and animal sera, and was used on a large scale in epidemiological studies and in the evaluation of immunity produced by various vaccines. More recently WHITMAN in Brazil with the intraperitoneal test [*ibid* 1943 v 40 534] and BUGNER in Colombia with the intracerebral test [*ibid* 1941 v 38 434] have devised modifications which have advantages over the standard intraperitoneal test.

For various reasons these tests proved unsatisfactory under the conditions present in Uganda, and it became necessary to find some satisfactory modification.

It is known that immature white Swiss mice are much more susceptible to the virus than older ones, the decline in susceptibility being rapid in the first three weeks of life but after that time slow. Infant mice are highly susceptible to intraperitoneal inoculation. This susceptibility decreases rapidly in the older mice, but can be enhanced 10- to 15-fold by a preparatory intracerebral infection of starch solution. The use of younger mice also means that less serum can be used than is necessary in standard tests with 6-week-old mice.

Smithburn found that not only were 7-day-old mice more susceptible than older mice to the virus, but also that antibody protects against more units of effective virus in them. Similarly in 14-day-old mice the titre of antibody in

a known immune serum was twice as high against 10 times the number of effective units of virus as it was in 35-day-old mice. This suggested that smaller amounts of antibody would be detected if weaker virus was used in the immature mice.

It was found that a serum which gives an inconclusive result against a relatively strong dilution of virus will give fully protective results if the balance between virus and serum is not too heavily weighted by the former.

In sera which had previously given inconclusive results with the standard 10 per cent virus test tests with 1 per cent. virus indicated that an occasional serum which originally gave a protection ratio of 0/6 may be protective that if one mouse survived originally there is an even chance that the serum is protective and that if more than one mouse survived it is almost certainly protective.

The final test decided on in Uganda uses 1 per cent. virus instead of 10 per cent as used by Sawyer and Whitman. If 3.0 ml or more of serum are available the tests are done in groups of six mice 5-6 weeks old. They receive an intracerebral inoculation of 2 per cent. starch solution and almost immediately afterwards receive intraperitoneally 0.6 ml of a mixture of 3.0 ml serum and 1.5 ml of 1 per cent virus. The mixture is not incubated prior to inoculation. If less than 3.0 ml serum are used the test is done in groups of 8-10 fourteen day-old mice comprising two litters. They do not receive starch inoculation. Each mouse receives 0.06 ml intraperitoneally of a mixture of 0.5 ml of serum and 0.25 ml. of 1 per cent virus. The results of these tests are interpreted as follows. If not more than 1 mouse dies the serum is considered protective. If not more than 2 mice survive the serum is regarded as non protective. If more than 1 mouse in a group die and more than two survive the result is regarded as inconclusive. Re tests are made on such sera whenever enough is available.

F O MacCallum

BUGHER J C The Effect of Prolonged Storage of Sera on Yellow Fever Protection Tests. *Amer J Trop Med* 1945 July v 25 No 4 333-8
2 figs [11 refs]

Yellow fever immune sera that had been stored in glass ampoules at Yaba, Nigeria, under very unfavourable conditions for more than 12 years were tested by means of the intraperitoneal protection test. Although the average loss of protective power seems to be about 50 per cent each year there were considerable individual differences and some of the sera still contained demonstrable antibodies. On the other hand in some instances the deterioration may be greatly accelerated. The velocity of deterioration seems to resemble that recorded by GLENNY in the case of diphtheria antitoxin [see *J Hygiene* (Camb) 1913 v 13 63].

Previously negative sera stored under the same conditions gave uniformly negative results [See also this *Bulletin* 1945 v 42 800] E Hinde.

DENGUE AND SANDFLY FEVER.

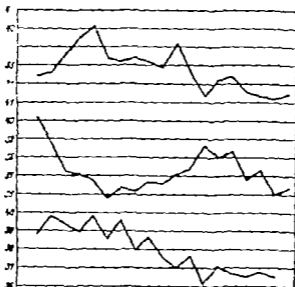

GOLDECK H & WALTHER R. Zur Frage des Russischen Kopfschmerzfiebers. [An Enquiry Into Russian Headache Fever] *Klin Woch* 1944 Feb 19 v 23 Nos. 5/8 59-61 3 figs.

This paper contains additional information regarding the problem fever Russian headache fever which is stated to have been common on the

eastern front during the recent war. No reference is made to the original description of the disease by SCHULTEN and BROGLIE [see this *Bulletin* 1944 v 41 127].

The author mentions the occurrence of 8 severe and 12 mild cases of the disease among 38 Russians in one camp. He saw about 50 cases but deals specially with 10 severe "meningeal" attacks in which stiffness of the neck was a prominent feature. The duration of the fever was 3-5 days in six, 7 days in two, and 8-10 days in two.

The cerebrospinal fluid was sterile on culture. It contained a considerable amount of albumin and numerous white cells mostly lymphocytes; the cell count ranged from 37 to 1 070 per cmm. It is stated that even in the mild cases the white cells were increased, the counts ranging from 10 to 100. The headache is described as being localized in the occipital region. There was pronounced bradycardia.

Temperature Curves in Russian Headache Fever
[Reproduced from *Klinische Wochenschrift*]

The three fever curves illustrating the paper show a striking resemblance to types commonly seen in dengue or sandfly fever and the author states that the curve was of the saddle-back type in more than half the cases.

No information is given with regard to epidemiological conditions connected with the occurrence of the disease even the seasonal distribution of the cases is not mentioned.

PLAGUE.

COMTE, L., POURSIÈRES Y. & MOUSTARDIER G. La peste expérimentale du cobaye et du rat blanc (données anatomo-cliniques) [Morbid Anatomy and Histology of Plague in the Guinea-pig and Rat.] *Méd Trop* Marseille, 1944 Mar-Apr v 4 No 2, 111-29 10 figs on 4 pls.

Five guinea-pigs and six rats were used and were inoculated intraperitoneally, subcutaneously and subconjunctivally with suspensions of 48-hour asepted

cultures. A number of photographs of the histological lesions in liver lungs suprarenals heart and kidney accompany the text. Three grades of acute lesions are distinguished. Necrosis and parenchymatous degenerations constitute the chief histological features in each organ and are recognizable in two types as toxic and septicaemic with abscess formation. *W F Harvey*

MATHUR W & GOYAL R. The Treatment of Plague with Sulphathiazole. *Indian Med Gaz* 1945 Aug v 80 No 8 383-5

Sulphathiazole has now become standard treatment in plague. It was used by the authors in 81 out of 120 patients along with some adjuvant treatment such as a tablet of nicotinic acid 15 minutes previous to each dose if nausea was pronounced or 10 per cent soluseptasine and 15 cc of 25 per cent glucose parenterally to combat toxæmia. Digitalis or coramine were additions if cardiac weakness set in. There were 17 deaths in all. *W F Harvey*

CHOLERA

SEAL S C The Problem of Endemicity of Cholera in Bengal. (A Plea for further Investigation.) *Indian Med Gaz*. 1945 Aug v 80 No 8 414-17 [10 refs.]

The author has himself taken part in the important researches on the epidemicity and endemicity of cholera which have been conducted in India for very many years. Answers were or are still required to the questions (1) What is a true cholera vibrio? (2) What is the best method of its recognition? and (3) What is its relation to other types of vibrio found in human beings water etc.? The Bengal Cholera Field Enquiry found that *V cholerae* could not be isolated from the stools of the general population or from water in the endemic area except in direct relation to the cholera case. Cholera is in fact transmitted from case to case and close contact carriers or water are only allowed infective agency for short periods and at short range. It is interesting to note that an area is classed as endemic if during the last 32 years there were not more than 30 months in which cholera deaths were not recorded and if the maximum period of absence of cholera records was less than 5 months. Many questions are presented for solution and for the most part the conclusion is reached that a final verdict is still awaited. The problem of primary importance in the epidemiology of cholera is the mystery involved in its endemicity. In question form this is put as 'Where and how does the cholera vibrio exist before a case occurs in the endemic area?' *W F Harvey*

BINSON G Etude des principaux caractères de 94 souches de vibrions et de quelques épreuves utilisées dans le diagnostic bactériologique du choléra. (Note préliminaire.) [*Vibrio Characters and Tests for Cholera.*] *Méd Trop* Marseilles 1944 Jan.-Feb v 4 No 1 32-48 [29 refs.]

A collection of 94 laboratory strains of vibrio were at the disposal of the author and have been tested diagnostically. They are classified as (1) isolated from cholera cases (2) of indeterminate origin (3) water vibrios and (4) El Tor vibrios (true and Macassar strains). This is a preliminary note and takes up specially—I Biochemical reactions (a) sugar fermentation and the classification of HEIBERG (b) the cholera red reaction (c) the Voges-Proskauer test II Haemolysis III OH agglutination and the thermostability test of

GIPSEN These are for the most part standard tests. Some of the conclusions may be recorded briefly in serial order —I Hellsberg's Group I is constituted essentially by agglutinable organisms from cases of infection with the true cholera vibrio. The cholera-red reaction is not a singular characteristic of the true cholera vibrio. A rather high probability value attaches to the Voges-Proskauer test in differentiating between the true cholera vibrio and the original El Tor but an exception has to be made for the Celebes strain of Macassar. II Haemolysis as a standard is much disputed, but affords a striking differential character with sheep erythrocytes capable of separating the non-haemolytic cholera vibrio from the haemolytic El Tor. III Agglutination does not separate the haemolytic vibrios especially the El Tor group from the non-haemolytic. The author lays very great stress on the Gipsen test because it is easy to carry out easy to read and economical of time which are very important considerations for the quarantine or frontier officer. This test is carried out as follows —An 18-hour agar culture is made into a dense suspension in a normal salt solution. One-half of this suspension is heated at 56–57°C for 3 hours and, when cool a comparison is made of the agglutinability of heated and non-heated suspensions kept at 46°C for 16 to 18 hours. Agglutination is read as being (a) with complete clearing, (b) with partial clearing or (c) with no clearing of the suspension. El Tor vibrios are completely thermostable and still show complete clarification, whereas vibrios isolated from cholera cases are thermolabile, that is, clarify only partially or not at all. The test should be a boon to the epidemiologist who has to apply detention measures to wayfarers with discernment.

PANJA, G. An Easy Method of producing Permanent Rough Variation in Cholera Vibrios. *Indian Med Gaz.* 1945 July v 80 No 7 342-3

Rough colonies of Inaba and Ogawa subtypes of cholera vibrios were obtained by growing the smooth vibrios on a nutrient agar plate containing atabrin (Bayer) in a strength of 1:5000. Rough colonies appeared after a few days and were replated on ordinary nutrient agar. Both variants appeared to be permanent.

J F Corson.

PANJA, G & GHOSH, S. K. Viability of Dysentery, Enteric and Cholera Organisms in Milk Curd (Dahi). *Indian Med Gaz.* 1945 Aug v 80 No 8 390-92

Curdled milk or *dahi* is a universal food throughout India and it may be sweet or sour. Both types contain lactic acid bacilli and have a pH ranging from 4.2 to 4.7. The efficacy of these bacilli or their acid product is widely appreciated. As a test 4 drops of culture of dysentery, enteric and cholera organisms were severally added to about 10 cc. of dahi, and subcultures were made at fixed intervals. Cholera vibrios were killed within 5 minutes, typhoid bacilli in times varying from 5 minutes up to a maximum of one hour while dysentery organisms required from 30 minutes up to 4 hours. An interesting comparison is made between lactic acid and other acids such as hydrochloric, acetic and citric with adjustment in all cases to pH 4.4. It was found that these other acids had a poor bactericidal effect by comparison with lactic acid on dysentery and typhoid organisms and that all of them except citric acid were highly and quickly bactericidal to the cholera vibrio. Tests with lime juice showed that at pH 4.4 and in dilution it kills cholera vibrios in half an hour and undiluted (pH 2.8) in 5 minutes, but has no effect on *Bact. flexneri* or *Bact. typhosum*.

W F Harvey

BACILLARY DYSENTERY

BOSE A N SEN GUPTA P N & BASU U P Sulpha Drugs in Bacillary Dysentery *Indian Med Gaz.* 1945 Aug v 80 No 8. 385-8 [19 refs.]

It is generally accepted that the sulphonamide drugs more particularly sulphaguanidine sulphapyridine succinyl sulphathiazole phthalyl sulpha thiazole and sulphanilyl benzamide and even sulphanilamide itself are more or less therapeutically beneficial in cases of bacillary dysentery. Sulphaguanidine is widely used, but it is costly and the dosage necessary is considerable its employment may be precluded by vomiting in those cases in most urgent need of it as it cannot be injected. Furthermore it is comparatively ineffective in *Bact dysenteriae* (Sonne) infections. Sulphapyridine is effective but causes nausea and vomiting and, possibly serious renal disorders if used in a dehydrating disease such as dysentery. Succinyl sulphathiazole is good, but again is inert against Sonne dysentery * while phthalyl sulphathiazole is of low toxicity and is highly effective against Flexner infections. The activity of these acyl sulpha thiazole drugs is dependent in part on their breaking down to sulphathiazole or at least to some compound containing a diazotizable amino grouping in the system.

Sulphathiazole was found, by the authors the best bacteriostatic agent of the series against a variety of dysentery organisms in culture. sulphapyridine and sulphanilyl benzamide were found to approximate in activity to it while phthalyl sulphathiazole was inferior to these but superior to sulphaguanidine. Succinyl sulphathiazole and sulphanilamide proved the least effective of these compounds when examined *in vitro*.

Sulphathiazole is relatively inactive against bacillary dysentery when given by the mouth as it is readily absorbed from the gut. Succinyl and phthalyl sulphathiazole prepared by acylating the *p*-amino grouping of sulphathiazole are less soluble less readily absorbed and more therapeutically effective.

Sulphanilyl benzamide although it is readily absorbed, has proved even less toxic but equally effective in the treatment of bacillary dysentery (including Sonne infections) in the hands of the authors who therefore conclude that the activity of a sulphonamide in intestinal infections cannot be judged solely as an inverse measure of the degree to which it is absorbed from the gut.

Inquiries are proceeding to find out the factors on which the action of these drugs against intestinal infections depends. They think that sulphanilyl benzamide may be the drug of choice in the treatment of bacillary dysentery.

A R D Adams

PANJA, G The Action of Drugs on Dysentery Bacteriophage. *Indian Med Gaz.* 1945 June v 80 No 6 294-5

Experiments were made to see whether drugs used for the treatment of bacillary dysentery interfere with the action of dysentery bacteriophage. The drugs tested were sulphapyridine sulphaguanidine solusoptasme phenol and electrolytic chlorine. The bacteriophage was used both concentrated and much diluted, and the drugs were used in two strengths the sulphonamide in 1 and 2 per cent solutions and suspensions phenol in 0.5 and 1 per cent solution and chlorine in 0.25 and 0.5 per cent solution. The drugs were kept in contact with equal quantities of the phage at room temperature for one or two hours then filtered through L_2 candles the filtrates were tested for the presence of phage by their effect on cultures of dysentery bacilli on a solid medium. The details are shown in tables.

In addition to the experiments with drugs dysentery phage was boiled for 2 and 5 minutes and tested similarly for activity.

[March, 1946]

The author concluded that these drugs have no action on strong dysentery phage and that boiling a strong phage for 5 minutes does not completely kill it.

J F Corson

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS.

English, R. B. Carriers of *Entamoeba histolytica* in Africans of Northern Rhodesia. *South African Med J* 1945 Oct. 27 v 19 No. 20 380

In the Northern Rhodesian copper-mining town of Luanshya, with a population of 2,500 Europeans and 30,000 Africans dysentery is almost exclusively of the bacillary type acute amoebic dysentery with trophozoites of *Entamoeba histolytica* being very rarely met with. Chronic amoebiasis in Europeans however appears to be becoming more common and causes anorexia, lassitude and inability to concentrate. Cysts are present in the faeces and the symptoms disappear with appropriate treatment. Because of this apparent increase among Europeans the author decided to determine the carrier rate among the African employees of the Roan Antelope copper mine.

Fresh preparations of faeces in saline and in Donaldson's eosin iodine mixture were examined microscopically. Cysts of *E. histolytica* were found in 170 (33.4 per cent) of the 509 Africans examined. Only 11 were minute forms.

The author mentions as interesting features of the local strain or strains of *E. histolytica* that (1) few cases of true amoebic dysentery occur (2) hepatic or other amoebic abscesses rarely occur (3) trophozoites of *E. histolytica* are rarely seen in Africans even in the frequent stools passed when they are suffering from bacillary dysentery.

The local forms of *E. histolytica* appear to have low virulence but since Africans are employed as domestic servants and handle food in European households, the high carrier rate among them represents a very definite public health problem.

J F Corson

ATZL, J. C. Incidence of Amoebic Carriers in Bombay. *Indian Physician* 1945 Nov. 4 No. 11 244-9 (23 refs.)

Out of 125 apparently healthy persons between the ages of 16 and 33 years, one faeces examination showed some protozoal and parasitic infection in 67 (53.6 per cent). 54 (43.3 per cent) had *Entamoeba histolytica*. In all these 54 cases the trophozoite stage was noted though cysts were present in some. The presence of *E. coli* and other protozoa was not particularly sought for but the former was detected in six along with *E. histolytica* and in four without. *Giardia intestinalis* was recorded three times and *Trichomonas hominis* once only. In nine cases ova of parasitic worms were found. The evidence available shows that, even though *E. histolytica* carriers as in this series are free from symptoms and are apparently healthy they should be regarded as clinically infected and consequently should be treated.

[The high percentage of trophozoites of *E. histolytica* in so-called carriers is against the testimony of experience of most workers, and certainly deserves further investigation.]

P Manson-Bahr

PATEL J C Incidence of Chronic Amoebiasis in Bombay and Non-Dysenteric Amoebic Abdominal Syndromes. *Indian Physician* 1945 Nov v 4 No 11 249-55

During 1944 101 stools of persons attending the Out Patient Department of the Singhanee Hospital Bombay were examined. These patients were suffering from symptoms related to the gastrointestinal tract. The presence of *E. histolytica* was particularly sought for other non pathogenic protozoa were not recorded. The dysentery amoeba was found in 58 in trophozoite form in 44 and in the cystic stage in 30 in 14 cysts alone were present. Of those with positive stools the youngest was six months old the oldest 55 years. The symptoms which varied in duration from a few days to 7 years were as follows —

Pain in the abdomen or diarrhoea vague pain most in the epigastrium or in the right or left iliac fossa flatulence and abdominal discomfort vomiting and hiccough low fever lassitude headache and giddiness lack of appetite stomatitis pain in the chest and back apathy and listlessness. In the case of females irregular catamenia and excessive leucorrhoea loss of weight

It is emphasized that chronic amoebiasis is more prevalent than is generally imagined and is responsible for chronic ill-health

[This paper represents the popular and widely-held attitude to amoebiasis and rests on a rather uncritical appreciation of symptoms which are common to a large section of the community in whom no evidence of protozoal infection can be obtained.]

P Manson Bahr

BIENKRANT W B GREENBERG M & MOST H Amoebiasis in a Hospital for the Insane. *Amer J Pub Health* 1945 Aug v 35 No 8 805-14 1 chart [13 refs.]

In an investigation carried out in a hospital for the insane by the New York City Department of Health over a period of 15 months 95 cases of amoebic dysentery were discovered among 5 575 inmates and employees. In mild cases diarrhoea was the chief and often the only symptom blood being absent from the stools and there being no fever. In severe cases diarrhoea was marked and the stools were frequent and in all cases blood was present many patients experienced abdominal cramps and all had fever. Examination of 1,822 persons showing no symptoms revealed 124 carriers of *E. histolytica*. Examinations were carried out on iodine and saline preparations of fresh warm specimens and on material concentrated by the zinc floatation method of Faust. In all 219 infections with *E. histolytica* were identified. Of these 61.5 per cent were found on the first examination, the second, third, fourth and fifth examinations bringing the percentages to 80.5 93 97.6 and 98.5 respectively.

Patients with amoebic dysentery were taken into hospital and treated in the following manner. A daily injection of emetine hydrochloride (0.06 gm.) for three days concurrently with chiniofon (12 tablets of 0.25 gm. each daily) for 10 days. After a 4-day rest period, carbarsone (one tablet of 0.25 gm. four times a day) was given for 10 days. In acute cases as distinct from carrier cases after a further rest period of four days a seven-day course of diodoquin was instituted (12 tablets of 0.2 gm. each daily). This completed what is described as intensive treatment on the 35th day. It is stated that clinical and laboratory cure was obtained in all cases. Presumably this refers to the immediate result for some months later there were 9 recurrences (or re-infections) 5 symptomless and 4 clinical cases. As regards infections among the inmates these were particularly high in those with poor sanitary habits. Of

[March 1946]

688 employees, 374 were inmate employees who gave an infection rate of 14 per cent. while the 314 paid employees gave a rate of only 8 per cent. It would seem inadvisable therefore to employ inmates in food-handling occupations. C. M. Wenyon.

KIRBY H. *Entamoeba coli* versus *Endamoeba coli*. J. Parasitology 1945 June v 31 No. 3 177-84 '33 refs.]

In this article the author has attempted to settle the controversy which has been waged for some years over the use of the two generic titles—*Endamoeba* and *Entamoeba*. He as others have done advocates the use of the former for the amoeba of the cockroach and the latter for the well-known parasites of man [this Bulletin 1945 v 42 327]. The following is his conclusion—
Opinion 89 of the International Commission on Zoological Nomenclature does not constitute proof that *Entamoeba* Casagrandi & Barbagallo 1893 cannot be used as a generic name. Its argument rests on two points that both, so that *Entamoeba* falls also as a synonym of *Endamoeba* Ledy 1879. The latter point which is the only one brought out in the summary of Opinion 89 is not acceptable. The Opinion asserts, but does not demonstrate that it is a homonym and there is nothing elsewhere in the Rules or Opinions that warrants the assertion. It is appropriate to place the species *coli* and *Blattis* in separate genera and it is considered that *Entamoeba* Casagrandi and Barbagallo 1893 is available as a generic name for *coli* and congenic species at the same time that *Endamoeba* Ledy 1879 is used for *Blattis* and congenic species. C. M. Wenyon.

SHIH LU CHANG. Studies on *Entamoeba histolytica*. V. On the Decrease in Infectivity and Pathogenicity for Kittens of *E. histolytica* during prolonged In Vitro Cultivation and Restoration of these Characters following Engraftment and Direct Animal Passage. J. Infect. Dis. 1945 Mar-Apr v 76 No. 2, 128-34 (3) refs.]

The author has studied two culture strains of *E. histolytica* from the point of view of their infectivity and pathogenicity to kittens. One strain lost its infectivity after 8 years of culture and remained non-infective for the following 3 years. The other strain became non-infective after 2½ years of culture. It was found that in both cases the loss of infectivity was associated with the cessation of encystment and that when encystment was again induced by transferring to encystment medium the infectivity was re-established. This infectivity which was evident after administration of material either orally or intra-caecally occurred only if the rectum was ligated. As plugging of the rectum was not sufficient it is concluded that the ligation did more than merely stop the passage of the intestinal contents. It appeared to alter the physiology of the intestine. When the infectivity of the first strain was re-established it was found that pathologically it was as active as it was originally. In the case of the second strain the pathogenicity was much reduced. It was regained to some extent by rapid passage from kitten to kitten. The bacteria associated with the pathogenic strain of *E. histolytica* were administered concurrently with the amoebae which had ceased to be infective. This failed to re-establish infectivity. When such a strain had regained its infectivity the administration of the virulent bacteria concurrently with the amoebae appeared to encourage the production of more severe lesions. C. M. Wenyon.

ZUCKERMAN Lucile K. & MELENEY H. E. A Fluid Medium for the Encystation of *Endamoeba histolytica* under reduced Atmospheric Pressure *J Parasitology* 1945 June v 31 No 3 155-7

To prepare the medium Cerophyl a commercial product made from the dried leaves of young cereal plants is extracted in CPR medium which consists of cholesterol one part per million and Difco proteose peptone 5 per cent. in Ringer's solution. The Cerophyl powder is added to the medium in a concentration of 2 per cent. The suspension is autoclaved and filtered and finally distributed in 50 cc. amounts in 250 cc. Erlenmeyer flasks. Just before inoculation with amoebae to each flask is added 5 cc. of inactivated horse serum and 0.02 gm. of specially prepared rice starch. After inoculation the flask is fitted with a rubber stopper and glass tube to enable the air pressure to be reduced to 40 mm. of mercury before incubation is commenced. It was found that without reduction of air pressure multiplication of amoebae prior to encystment was limited. By the use of this medium for over a year 100 flasks gave an average count of close on four million cysts per flask. C. M. Wenyon

MELENEY H. E. The Relationship of Clinical Amoebiasis to various Strains and Growth Requirements of *Endamoeba histolytica* *Puerto Rico J Pub Health & Trop Med* 1944 Sept. v 20 No 1 59-70 [Refs. in footnotes] [Spanish version 71-83]

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

PAVLOVSKI E. N. & SKRUINNIIK A. N. [On the Period during which Females of *Ornithodoros papillipes* are able to transmit the Tick Relapsing Fever] *Zool Zh. Moscow* 1945 v 24 No 3 161-4 English summary [In Russian.] [Summary taken from *Rev Applied Entom* Ser B 1945 Nov v 33 Pt 11 165]

Of a batch of 24 nymphs and adults of *Ornithodoros tholozani* Lab & Mégn. (*papillipes* Bur.) taken in October 1931 in a cave near Stalmabad (western Tadzhikistan) and brought to Leningrad 14 were alive in February 1933 ten in May 1934 six in April 1935 three (all females) in October 1940 and two in January 1941. During these years the ticks were allowed to feed at intervals on laboratory animals and they transmitted spirochaetes of relapsing fever with which they were naturally infected, to guinea-pigs and *Dryomys miedula*. In September 1941 the two surviving females were sent in a thermos flask to Samarkand, where they arrived in October 1942. They had not fed for about two years and one of them was dead in the following month. The other was taken back to Leningrad in June 1944 together with an adult male that had been found in western Kirghizia in 1935 and both were allowed to feed on a guinea-pig in October 1944. The latter subsequently showed spirochaetes in its blood and as the male had failed to infect laboratory animals on any of the occasions on which it had fed alone it is concluded that they were transmitted by the female.

Previous investigations by the authors have shown that *O. tholozani* can live for up to 25 years and can resist starvation for up to 7½ years. Its long life, the fact that spirochaetes persist in it from generation to generation its wide range of hosts other than man and domestic animals and its tendency to move about little ensure the preservation in nature of foci of relapsing fever.

WISSEMAN C. L. Jr. Relapsing Fever in Denton County Texas. Report on finding the Tick, *Ornithodoros irritans* Naturally Infected. *Amer J Trop Med* 1945 July v 25 No 4 339-42, 2 figs. [10 refs.]

The author has succeeded in finding *Ornithodoros irritans* infected with relapsing fever spirochaetes, in a cave near Roanoke Denton County Texas. It may be recalled that although this cave was suspected of being responsible for a number of human cases of relapsing fever [see this *Bulletin* 1935 v 32, 296] previous investigators had failed to find any infected ticks.

Three trips were made to the cave and each time ticks were collected from the sandy floor. Two members of the first party found ticks on their bodies, and seven days after being bitten one of them developed a typical attack of relapsing fever. Nine ticks were fed on a human patient undergoing pyretotherapy and after five days he showed spirochaetes in the blood and had 4 relapses at intervals of 3 to 5 days. Spirochaetes were present during each febrile attack.

White rats were readily infected by the inoculation of blood from both human cases. E Handle

JARVIS J. F. Relapsing Fever in an Infant of Five Days. *East African Med J* 1945 Sept. v 22, No 9 311

An African woman was admitted to Morogoro Hospital, Tanganyika Territory on April 9th 1945 developed relapsing fever on April 13th and gave birth to a child a few hours afterwards. Spirochaetes were present in her blood. The child remained apparently well until the 5th day when it also developed relapsing fever and died next day in spite of having received a dose of 0.015 gm. of neosarsphenamine (N.A.B.).

The author thinks that the mother might have been infected in February as she gave a history of having had fever about that time or she might have been bitten by a stray tick while in the hospital between April 9th and 13th. He suggests that the child might have been infected from the mother through the placenta, or by entry of the maternal blood into an abrasion or the cut cord could infection by a stray tick be excluded? J. F. Corson.

CHARTERS A. D. Louse-borne Disease. [Correspondence.] *East African Med J* 1945, Sept. v 22, No 9 303-9

WOLMAN this *Bulletin* 1945 v 42, 469 found that an Italian preparation of neosarsphenamine (Neo I C I) had little effect on louse-borne relapsing fever in Addis Ababa Abyssinia. Charters however who used an allied arsenical preparation called "Neocal" at Sodda, Abyssinia found that after a dose of 0.6 gm. intravenously clinical improvement took place within 24 hours, spirochaetes could no longer be found in thick blood films after 8 hours, and no relapses occurred. He suggests the following possible explanations of the difference in the results: (1) Wolman's patients were probably treated later in the attack than the author's who were Gold Coast soldiers. (2) some of Wolman's cases, regarded as "first attacks" may have been relapses. (3) natives of the endemic district (Wolman's patients) may possibly respond less readily to the arsenical drug than new arrivals (Gold Coast soldiers). He thinks that the first explanation is the most important of the three. In his experience arsenical drugs have far greater effect on louse-borne relapsing fever than on the tick-borne form. J. F. Corson.

LEPROSY

BECHELLI L. M. KEIL H & ROTBERG A. Resultados da lepromino-reação em países não endêmicos de lepra. (Nota preliminar) [The Lepromin Reaction in Countries where Leprosy is not Endemic.] *Rev Brasileira Leprologia* São Paulo 1945 Mar, v 13 No 1 21-4

BARGEHR DE LANGEN and others in the Dutch East Indies have reported positive lepromin reactors among apparently healthy individuals in contact with lepers contrasting them with recent arrivals who do not react. It is inferred therefore that the lepromin reaction is an indication of a prior latent infection with production of specific antibodies. Children removed at birth from their leper parents react negatively.

The authors have tested the Mantoux reaction and the early and late lepromin reactions in patients at the Skin and Cancer Unit of the New York Post Graduate Medical School and suffering from conditions other than leprosy. Twelve had been born and had lived for part of their lives in places with very low leprosy incidence. 36 had lived for a time in places where the disease was endemic. The results of each test are given in tables and the conclusions to be drawn from them are that a delayed lepromin reaction does not necessarily indicate a latent infection but may be regarded as allergy to the lepromin injected 3-4 weeks before. WADE has remarked on the positive reaction to lepromin in persons who had not been previously in contact with lepers and he explained this by saying that such persons can react allergically to Hansen's bacillus when they come into contact with it. From the results recorded in the tables the early reaction does not necessarily indicate either latent infection with leprosy or sensitization to lepromin, for it may occur in 6-12 hours. It is thought that tuberculosis is responsible for all but one of those tested who gave the early response were also Mantoux positive. The early lepromin reaction therefore must be regarded as non specific and due to sensitization to *M. tuberculosis*.

AMENDOLA F. A glândula lacrimal na lepra ocular [The Lachrymal Gland in Ocular Leprosy] *Rev Brasileira Leprologia* São Paulo 1945 Mar v 13 No 1 3-11 1 pl.

The lachrymal glands orbital and palpebral by continual secretion of tears when infected by leprosy constitute an important focus of infection. Bacteriological examination often shows these to be infected in leprosy and their extirpation thus removes one focus of infection. In patients where other eye lesions are present even though the glands do not appear to be involved removal of them is often followed by marked improvement of these other lesions. This last was observed in three of the 20 cases briefly detailed in this paper. Thus one a woman of 18 years had extensive keratitis of one eye and of one third of the other with photophobia and epiphora. she was very depressed about her eyes and all kinds of medical treatment had been tried ineffectively. Extirpation of the lachrymal glands was performed. histological examination of sections failed to reveal Hansen's bacteria. Nevertheless a few days later the patient presented herself without pain or photophobia, happy and cheerful and hopeful of complete cure. Two months after the operation the benefit was maintained. The author is hopeful that the operation may prevent much of the suffering and ultimate blindness which now afflict so many lepers.

GONZÁLEZ PRENDES M. A. & IBARRA PÉREZ R. Duración de la lepra. [The Duration of Leprosy] *Rev. Sifilografía, Leprología y Dermatología* Marianao Cuba, 1945 Oct. v. 2, No. 3 175-9

Duration of illness in this disease is very difficult to assess as it depends on so many factors, among them the treatment adopted whether it is begun early or late whether it is carried out rigorously or half-heartedly whether the surroundings are hygienically sound, whether the general state of health of the patient is good the appetite faith in the success of treatment and other matters. JEANSELMÉ gives the duration as 10 to 20 years RODRIGUEZ up to 40 years MIRANDA from a study of 552 patients who died, gives "an average of over ten years" and many have stated it to be over 20 years and occasionally as long as 40 and even 50 years.

The authors have tried to assess the average duration from a study of 270 cases. They found that 43.3 per cent. discovered symptoms between the ages of 16 and 30 and 15.1 per cent. between 16 and 20 years. The average age at which they became ill was 25.7 years, and assuming that the incubation period was five years (a big assumption) the average age at first infection is given as 20.7 years. In 121 cases (44.8 per cent.) the average duration was 16-25 years (including incubation) and 62 were in the 16-20 years group. The average duration of the whole 270 worked out at 23.15 years [we give the authors figures they are not easy to reconcile with the details in the tables presented]. As extremes, one patient died in three years and another after 56 years illness. The greatest number of deaths occurred between the ages of 36 and 45 years with an average of 43.8 years. *H. Harold Scott*

LIMA L. de S. & CERQUEIRA, G. de C. Terapêutica experimental da lepra pela solutiazamida. Nota prévia [Trial of Solutiazamide in the Treatment of Leprosy] *Publicações Médicas* São Paulo 1945 June-July No. 154 3 5-7 9-11 English summary

Solutiazamide is p (γ-phenyl-propylamine) phenyl-sulphamido-thiazole-α-γ disulphonate of sodium. It is used in 45.3 per cent. solution, which contains 20 per cent. of thiazamide base. A 5 cc. ampoule contains 1 gm. of thiazamide. Most concentrated sulphonamides have a pH between 9 and 11.4 and thus degree of alkalinity causes eschars solutiazamide has not this drawback. Trials with it for leprosy have been going on for 8 months this is too short a time for a definite appraisement of its therapeutic value but the results so far as reported by the authors are sufficiently promising to warrant more extensive testing.

Their clinical material comprised 100 cases, 50 with lepromata in a comparatively early stage and 50 adults with severe lepromatous forms and extensive involvement of the skin in whom chaulmoogra had proved ineffectual. The drug was administered intravenously each day except Sundays, for 3 weeks, the course being repeated after a week's interval the initial dose was 1 cc. which was increased gradually to 5 cc. and in adults to 10 cc. Those receiving more than 5 cc. were given also an equal amount of glucose solution.

The results observed so far comprise coagulation of leprotic ulcers and of conglomerate lepromata, disappearance of lepromatous infiltrations and softening of subcutaneous nodules perforating ulcers of the sole sometimes

improved and ocular symptoms after a brief period of exacerbation showed considerable amelioration and had not relapsed during the time that patients were under observation the nostrils became clearer less obstructed crusts disappeared and respiration was freer

Examinations of the blood and urine were carried out systematically during the treatment The red corpuscles were counted and the haemoglobin estimated before the treatment started and every ten days afterwards If the red cells fell to 4 million per cmm. iron was given if between $3\frac{1}{2}$ and 4 million liver extract was ordered if lower still soluthiazamide treatment was suspended and the anaemia treated until the blood returned to normal then it was restarted with small doses and gradually increased If albumin or red corpuscles appeared in the urine the treatment was temporarily suspended *H Harold Scott*

OCKULY E. A. Bilharziasis of the Bladder (Vesical Schistosomiasis) *J Urology*
1945 July v 54 No 1 39-45 1 fig [25 refs.]

This is a record of the first case of urinary schistosomiasis detected at the Army Air Forces Regional Station Hospital No 1 in Florida. The patient a sergeant aged 22 was infected in North Africa or Sicily was diagnosed cystoscopically as suffering from a tumour of the bladder and was invalided to the U.S.A. The correct diagnosis was there eventually established by cystoscopic biopsy and subsequently confirmed by the rather simpler procedure of urine examination which revealed eggs of *S. haematobium*

The patient was cured with Fouadim. The author discourses [at times loosely] on urinary schistosomiasis and stresses the possibility of other members of the forces being found to be infected on their return to the United States.

KRAKOWER, C. HOFFMAN W. A. & AXTMAYER J. H. Granulación en la cubierta de los huevos de *Esquistosoma mansoni* (Experimentación con cobayos esquistosomizados y alimentados con una ración deficiente de vitamina C.) [Granulation of the Shell of the Ovum of *Schistosoma mansoni* An Experiment with Infected Guineapigs fed on a Diet deficient in Vitamin C.] *Puerto Rico J Pub Health & Trop Med.*
1944 June v 19 No 4 669-78 2 pls.

One hundred and thirty nine guineapigs each weighing 200-400 gm. were each infested with about 4 000 cercariae of *Sch. mansoni*. They were then divided into five lots. Four were given the following diet deficient in vitamin C. Rolled oats 59 per cent. powdered skim milk 30 per cent. heated in trays to 10°C. for an hour 10 per cent. butter and 1 per cent. NaCl. Three of the lots

[March, 1946]

were given thrice weekly injections of ascorbic acid, the total weekly dosage being 3.9 and 25 mgm. respectively. The other lot had no vitamin. The fifth group was fed on green food.

All those on a scorbutic diet died within a month or were killed at the end of that period, i.e. before oviposition had occurred. In these animals the parasite had undergone no change in growth or development. The same was observed in the group receiving 3 mgm. ascorbic acid weekly. Disintegrated ova were rarely seen in those receiving 9 mgm. Of 50 animals showing the ovular changes 28 lived for more than 5-6 weeks after being infested. The last one was killed after 109 days. Many of these guinea pigs showed signs of scurvy and in the 26 the schistosome ova seen in sections of tissue from the liver and lungs were disintegrating. The shells were swollen, sometimes laminated, eroded and granular and around them histocytes, giant cells and perhaps lymphocytes eosinophils and polymorphonuclears. In the last stages the shells became granular with greenish refracting granules single or grouped.

To confirm these observations a lot of 12 guinea pigs ten weeks after infestation were gradually transferred from their green food to a scorbutic diet and 7-9 days after being on the latter they were passing ova with disintegrated shells and these increased in number till at the end of four weeks half the eggs seen in sections of the liver had disintegrated shells. Such ova were very rarely seen in those receiving 9 mgm. ascorbic acid weekly added to the scorbutic diet or a diet with insufficient antiscorbutic addition. Briefly the effect of a scorbutic diet or a diet with insufficient antiscorbutic addition was to reduce gradually the number of eggs produced and the eggs themselves seemed to undergo a lytic process whereby the shell became granular while the surrounding tissue showed a certain degree of fibrosis.

ELSAESSER, K. H. Zur Symptomatologie Diagnostik und Therapie der Hirn cysticercose. Bericht über 8 Erkrankungen und tabellarische Zusammenstellung der Fälle des Schrifttums seit 1910. [The Symptoms, Diagnosis and Treatment of Cerebral Cysticercosis. An Account of Eight Cases and a Table of Cases recorded since 1910.] Ztschr. f. d. Neurologie u. Psychiatric 1944 July 25 v 177 No 3 323-62, 8 figs. [Numerous refs.]

An article of much importance to all neurologists and not only to tropical practitioners. The author records in detail 8 cases of cysticercosis of the brain under his own observation and reviews a large number of cases reported in the last 34 years. The condition is very likely to be missed because the symptoms are not at all definite (see later) and even more because the suspected he urges the importance of bearing the possibility in mind by those practising in districts where it is liable to occur and by any medical man called upon to treat patients who have been stationed, or have lived in areas where the infestation exists.

At the author's clinic only 8 cases have been seen in the 12 years 1931-42 inclusive 6 in men and 2 in women. During that time some 20 000 patients have been seen among them 2,500 neurological cases of these there were some 900 with signs and symptoms of cerebral tumour so that there has been an average of one case of cerebral cysticercosis in every 125 of tumour.

There is no need here to detail the symptoms in each case there is a general type common to all in which the symptoms are those associated with hydrocephalus in the adult headache early and persistent especially occipital and extending down the neck giddiness nausea and vomiting. These symptoms are usually aggravated by head movement so the head is held steady as a rule fixed to one side and movement is restricted or carried out very cautiously. This goes by the name of the Bruns symptom. There may be affections of gait and of sensation but these are rare and not in any way characteristic psychically patients are mentally dull but often euphoric. The duration of illness is difficult to assess because many show neurasthenic symptoms for some years which may of course have no connexion with the symptoms psychic and other due to the cysticercosis. Also some patients have intervals of improvement when symptoms may almost be absent for varied lengths of time. In a table of 63 cases with cysticerci situated in the basal meninges the duration of symptoms is recorded as short several weeks to as long as 26 years in one case recorded by GUILLAIN PÉRISSON in 1927 [but not mentioned in the list of references]. Of these 63 forty (perhaps more) presented psychic disturbances of one kind or another. Others might be merely apathetic or show Korsakov's syndrome paranoia, depression or hyperaesthetic emotional states.

Diagnosis is not easy because symptoms are in general so vague. Rarely lumbar cisternal or brain puncture may result in finding fragments of a parasitic cyst. They tend early to calcify and then X-rays will reveal them. The cerebrospinal fluid may show 2-3 per cent. of the cells to be eosinophiles.

A favourite site for the cysts is the fourth ventricle. The author gives a list of 41 in which this was the case and in a few there was a combination of fourth ventricle and basal meningeal infestation. Information in this list includes the name of the author reporting the year of record the sex and age of the patient the chief clinical symptoms and the duration of the illness so far as this could be determined it ranged from a few days to perhaps 30 years. The ventricular cases are characteristically those which have an acute ending. The cysticerci are said to pass from the choroid plexus to traverse slowly the third ventricle and the aqueduct and, having increased in size are unable to penetrate the narrow slit like lateral apertures to the foramen of Magendie. They are usually monocular rarely of the racemose type. If the cyst dies it becomes shut in by neuroglial fibrosis and then acts like a neoplasm. Pressure symptoms comprise a medium degree of papillary oedema on both sides but only a few patients have serious disorders of vision in a fair number there is slight paresis of the 3rd and 6th cranial nerves cerebellar ataxy is seen in about one-fifth of the patients epileptic attacks in one tenth but more in the basal meningeal cases than in those with ventricularly situated cysticerci. Operation is the only satisfactory line of treatment.

MUKERJI A. K. & SEN GUPTA, K. K. Effect of Heat and Light on the Ascaridole Content in Oil of *Chenopodium*. *Indian Med Gaz.* 1945 July v 80 No. 7 747-8.

MUKERJI and GHOSH [this *Bulletin* 1943 v 40 922] showed that when oil of *chenopodium* is kept at temperatures of from 70 to 93°F., whether exposed to light or kept in the dark its ascaridole content decreases. To find the best way of storing the oil the authors of the present paper made experiments in which they kept samples in glass-stoppered bottles for one year under various conditions of temperature and exposure to light, the ascaridole content being determined at 2 4 6 and 12 months.

The smallest amount lost was in the samples which were kept in subdued light at 65-75°F. and the authors conclude that oil of *chenopodium* is best stored in a cool place where the temperature does not rise above 75°F. and where there is protection from direct light.

HERNÁNDEZ MORALES F. & DIAZ RIVERA, R. Poisoning by Carbon Tetrachloride and Oil of *Chenopodium*. *Puerto Rico J. Pub Health & Trop Med* 1943 June v 18, No 4 434-42. [Refs. in footnotes.] [Spanish version 443-51]

Three cases of poisoning by a dose of a mixture of carbon tetrachloride and oil of *chenopodium* are described. The patients were white Porto Rican labourers aged 31 36 and 35 years, respectively and the circumstances were similar in all. Each man took a mixture of 2 cc. of carbon tetrachloride and 1 cc. of oil of *chenopodium* [a well recognized therapeutic dose] in the morning on an empty stomach, and immediately afterwards took 60 gm. of magnesium sulphate. The first two men were admitted to hospital two days later and the third man three days later. In addition to the clinical examination, the urine and blood were tested at short intervals in the laboratory and the findings are shown in tabular form.

The symptoms were similar in all. An hour or so after taking the dose the patient had vomiting and diarrhoea with pains in the abdomen headache and general body pains and in two cases cramps in the arms and legs. Tenderness over the liver was present in all and two showed jaundice and enlargement of the liver the lower edge being palpable three fingerbreadths below the right costal margin.

The urine was scanty in amount in all three but showed only traces of albumin and few casts, and the specific gravity was very low. The reaction was acid. In the third case in which the effects of poisoning were the most severe the amount of non-protein nitrogen of the blood is given as 200 mgm. per cent on the day after admission 300 mgm. four days later declining gradually to reach 40 mgm. on the 25th day after admission.

The patients were treated similarly. They were given a high carbohydrate diet calcium gluconate and glucose solution were administered intravenously and calcium lactate was taken by mouth. All recovered and were discharged from hospital on the 16th 19th and 27th days respectively after admission.

The authors quote the views of various authors on the mode of action of the drugs and remark that it is difficult to decide which of the two drugs caused most damage, but they think that carbon tetrachloride caused most of the symptoms.

BUCHANS R. A. Filariasis in the Armed Forces. *J Urology* 1945 July v 54 No 1 59-61

Before the recent war Bancroftian filariasis was associated in the minds of most medical men chiefly with pictures of elephantoid scrota or limbs. The author states that these conditions result only from years of constantly repeated infection and that few if any cases will be encountered in men of the U.S. forces serving in the South Pacific area. He wishes to allay the anxiety inspired by inspection of the text book pictures by medical practitioners at home and by anxious relatives of which he says the end results on morale are terrific.

In actual fact the findings in men returned to the U.S.A. with a diagnosis of filariasis have been minimal and he observes that sterility does not result from the infection. He offers some observations on the aspects of filariasis from the urological standpoint.

A R D Adams

RAO S S. Filarial Infection in Dhamda (Drug District, O.P.) due to *Wuchereria malayi*. *Indian J Med Res* 1945 May v 33 No 1 175-6

Dhamda village is 21 miles north of the town of Drug Central Provinces India and has a population of 3 628. The author took thick blood films between 9 p.m. and midnight from 120 persons in February 1942 and found microfilariae of *Wuchereria malayi* in 16 (13.3 per cent). A survey of the village population at the time showed that there were 80 cases of elephantiasis of the legs or hands (2.2 per cent) but no cases of hydrocele, chyluria, lymph varix or elephantiasis of the external genital organs were observed.

During the period of the survey the following mosquitoes were prevalent in the village: *Mansonioides annulipes* [= *longipalpis*], *M. uniformis*, *Culex fatigans* and *Anopheles culicifacies*. All the big tanks were full of *Pistia stratiotes* and *Mansonioides* bred there. Among the mosquitoes dissected *Mansonioides annulipes* alone showed filarial infection and this therefore appears to be the most important local vector. [See also this *Bulletin* 1937 v 34 33. *Indian J Med Res* 1940 v 28 609.]

J F Corson

McMARTIN W J. Urological Aspects of Filariasis. *J Urology* 1945 July v 54 No 1 62-74 [16 refs.]

After brief and lucid accounts of the history, geographical distribution, aetiology, pathology, symptomatology, diagnosis, psychiatric aspects and treatment of Bancroftian filariasis the author cites six cases of the many he has seen in service hospitals in the U.S.A. illustrative of the distribution of the lesions as classified by HUNTINGTON, FOGEL, EICHOLS and DICKSON (*Yale J Biol & Med* 1944 v 16 529).

He ends with the following reassuring conclusions —

Filariasis has infected thousands of our armed forces located in the Pacific area.

The disease in these men is characterized by episodes of lymphangitis and lymphadenitis with the majority of the patients showing genital (scrotal) involvement.

Civilian urologists will be confronted with the problems of differential diagnosis of intrascrotal pathological changes caused by filariasis as well as intrascrotal pathological changes usually encountered in the United States.

There are many members of our armed forces who have filariasis and fear the onset of elephantiasis despite attempts of medical officers to dispel their fears. We can do a great deal to ease these patients' minds by educating them on the characteristics of the disease.

There is no specific drug in the treatment of filariasis. Removal of the patient to a temperate climate and away from the chance of more infection is most important.

"Rest elevation of the affected parts and cold applications is the treatment of choice in episodes of exacerbations of the disease.

Research on the treatment of filariasis is constantly being carried out by very competent medical personnel of the Army and Navy. Excellent results of this work may be reported in the literature soon.

Much will be added to the knowledge of the pathology of early filariasis when and if complete post mortem examinations can be done on patients who have filariasis or who give a history of having had filariasis at some time during their life.

Filariasis will not become a public health problem in the United States.

"Permanent disability as a result of filarial infestation among our armed forces will be a rarity.

The Army and Navy Medical Corps have progressed rapidly towards eradicating this disease.

ROSE, H. M. CULBERTSON J. T. & LIPMAN Miriam O. Antistreptolysin Titers in Cases of Filariasis with Recurrent Lymphangitis among Military Personnel. *J Clin Investigation* 1945 July v 24 532. [Summary taken from *J Amer Med Ass.* 1945 Nov 17 v 129 No. 12, 830-31.]

Rose and his co-workers determined antistreptolysin titers in the blood of 45 soldiers suffering from recurrent lymphangitis associated with filariasis contracted in the South Pacific. The titers were within normal limits in 39 of the 45 cases. The attacks of lymphangitis in these soldiers appeared to be due to allergic reactions to the parasitic infection: secondary streptococcal infections were of little or no consequence as an etiologic factor.

WILLCOX R. R. Genital Oedema in relation to Filariasis in the Gold Coast. *Brit J Tropical Dis.* 1945 Dec. v 21 No. 4 178-9

Oedema of the external genital organs was present in 10 out of 875 African soldiers admitted to a hospital at Accra, Gold Coast between June and September 1944. Examination of the blood showed microfilariae of *Loa loa* in 5 and microfilariae of *Acanthocheilonema perstans* in 1. Microfilariae of *Onchocerca volvulus* were found in the skin of 1 man who had also a guinea-worm the scrotum. Some of the 10 men gave a history of having had several attacks of genital oedema.

Treatment was by means of a suspensory bandage and in 4 cases the swelling subsided within a week. One was operated on for elephantiasis of the penis and scrotum. [The incidence of filarial infection among the other 775 soldiers is not given.]

WANSON M. & HENRIARD C. Habitat et comportement larvaire du *Simulium damnosum* Theobald. [Habitat and Larval Development of *S. damnosum*.] *Rec Travaux Sci Méd Congo Belge* 1945 July No. 4 113-21

This gives a detailed account of the ecology of *Simulium damnosum* in the neighbourhood of Léopoldville in the Belgian Congo. The biting of these

insects constitutes a serious nuisance during the months of September to January (i.e. the start of the hot season) *S. damnosum* is also the vector of *Onchocerca volvulus*

The adult females migrate to the town from the rapidly running sections of the river by the way of shaded water-courses. They commonly migrate for several miles (45 miles is quoted as a maximum). Breeding goes on in various locations in the rivers the larvae and pupae being attached to stones submerged plants and wicker work fish traps. A sudden change in water level causes a high mortality but a gradual rise or fall allows the larvae to migrate to a suitable situation. The life-cycle from egg to adult takes about nine days and the adult female lives about three weeks. In certain regions *S. damnosum* is frequently parasitized by microsporidia this causes a substantial mortality

WANSON M. HENRARD C. & PEEL E. *Onchocerca volvulus* Leuckart. Indices d'infection des simuliés agressives pour l'homme. Cycle de développement chez *Simulium damnosum* Theobald (*O. volvulus* Indices of Infection of *Simulium* and Cycle of Development.) *Rec Travaux Sci Méd Congo Belge* 1945 July No 4 122-38 8 figs. on 1 pl.

Simulium damnosum and *S. albivirgatum* both attack man in the Belgian Congo but only *S. damnosum* is of importance as a vector of *Onchocerca volvulus*. The population of fishermen living near the rivers in which the vector insects breed is heavily infected (up to nearly 100 per cent) and 15 per cent of *S. damnosum* captured from their villages were infected. In villages five miles away from the breeding sites 65 per cent of the people and 8 per cent of the *Simulium* were infected. Further afield the infection rate in both man and insects declined still more.

Adults of *S. damnosum* have been kept alive in the laboratory for over a week in sufficient numbers to demonstrate the whole cycle of *O. volvulus*, which takes six or seven days.

SCHUFFNER W. Die Bedeutung der Staubinfektion für die Oxyuriasis. Richtlinien der Therapie und Prophylaxe. [The Importance of Dust-borne Infection in Enterobiasis. Rules for Therapy and Prophylaxis.] *Munch med Woch* 1944 Aug 11 v 91 Nos. 31/32 411-14 [Numerous refs.]

Infestation experiments on seven persons (doctors and students) enabled SCHUFFNER and SWELLENGREBEL to show that eggs of *Enterobius* which had dried for three days and longer in room dust retained their full

powers of development. Six out of the 8 subjects passed worms after 36 to 53 days—that is to say the shortest time required before worms were passed was 36 days and the longest 53 days. Thus dust-borne eggs are a source of infestation [cf also CRAM this *Bulletin* 1943 v 40 618].

The large numbers of eggs found by Schöffner and Swellengrebel [this *Bulletin* 1945 v 42, 924] in the dust of a school dining hall leaves no doubt of the importance of this source of infestation.

Eggs may get into the dust in various ways. LEUCKART thought that the eggs dry with the faeces because the female worms lay their eggs on the outer surface of the faeces—but it is doubtful whether these eggs play any part in the distribution of the worms. Most of the faeces are deposited in the closet and do not dry. The eggs in the very small amount of faeces deposited in the outer world are so much diluted by the atmosphere that hardly one of them will find a host. The main source of eggs in dust is the anal region which is also the main source of finger infection. From the anal region eggs pass into the air not singly but in clusters.

Many eggs which pass into the unenclosed atmosphere are lost or fail to develop—but within enclosed spaces the air can carry a wide variation of numbers of eggs. In one school studied by the author the number of eggs found on about 10 sq decimetres (q d.m.) [roughly 1 sq foot] of surface was 119 in a large dining hall, 305 in classrooms and about 5 000 in the much smaller closets. The size of the room is not the only factor which affects the density of eggs found. SMALT (*Nederl Tijdschr v Geneesk* 1944 p 20) found that the egg content in female closets was greater although the worm infestation of the females was not higher than that of the males. Doubtless dissemination of eggs is favoured by the movements of female clothes.

The spaces just mentioned are, however, used only for a short time. There is a much smaller air space which is used for half the life of the infested person namely the air space under the bed clothes. This has been studied by OLENIKOFF (*Russ. J Tropenmed u med u vet. Parasitenk* 1929 p. 399). This space is an important source of dust borne infestation for the eggs are disseminated night after night by the movements of the sleeper and can often enter the nose and mouth in considerable numbers. This is especially a risk for males who tend to draw the bedclothes over their heads more often than females do and this may explain why males, in spite of all precautions and repeated drug treatment are not freed from their infestations. Eggs are also distributed from the bed into the air by bedmaking.

Dust borne infection plays an important part in the epidemiology of enterobiasis. It does not cause heavy infestations which arise from finger infestations only but it introduces enough eggs to cause repeated light infestations. Finger infection may be added to it and then severe enterobiasis may arise. It is important to differentiate between these two kinds of infestation. The hypothesis of an enterogenous development of *Enterobius* within the alimentary canal has been suggested to explain repeated infestations and failures to cure but dust-borne infestation can explain these more simply and equally well.

Schöffner's own experiments show that in all the persons studied by him, the infestations, which lasted 12 to 27 days, ceased without treatment. The same result appears to have been obtained in the twelve experimental infestations with fresh eggs recorded in the literature [no refs. are given], although this was not always explicitly stated. In one person only experimentally studied by v DRIGALSKI and KOCH, (*Deut. med. Woch.* 1925 p 309) did the infestation reappear after nine months, in spite of every care. In this instance dust-borne infection was responsible for the reappearance of the infestation. Without it *Enterobius* dies out. In the author's experience its length of life is 37 to 83 days.

Preventive measures should be based upon a distinction between management of the individual suffering from active enterobiasis and general measures directed against carriers who exhibit inactive (latent) enterobiasis (see HAMBURGER *Mituch med Woch* 1943 p 723). For latent enterobiasis there is no treatment hygiene thereby acknowledges its weakness we can only try to limit the degree of the infestation. In active enterobiasis the intensity of the irritation may vary not only with the number and vigour of the worms but also with the sensitivity of the subject some subjects who are not ticklish may suffer little from even an active enterobiasis (e.g. one of the persons used experimentally by Schüffner). In active enterobiasis also dust borne infestation is of capital importance. It has hitherto been much underestimated it provides a gap in the control plan which is responsible for failures in treatment. It is useless to enforce severe hygienic rules if dust borne infestation is not also controlled. The rule is to treat the symptoms only and to do this by the simplest means. Schüffner recommends for this purpose small enemas (*Einduse*) of 30 to 50 cc. of water for the temporary appeasement of the anal irritation. These wash out the worms in the anal area. Inspection of the rectum at the height of the irritation shows active worms in the anal folds. When these are removed the irritation ceases at once. The view of LORENZ (*Med Klin* 1925 p 95) that the irritation is due to larvae of *Enterobius* is not correct because the larvae are too small and Schuffner saw them hatch in the anal region only very exceptionally. Schüffner agrees that some larvae may hatch here and creep back to continue their development in the intestine as LANGHANS (*Arch. Kinderh* 1926 v 77 27) suggested but he has as yet not enough evidence to prove it this is at any rate not true enterogenous development but merely avoidance of the usual entry by the mouth.

Small enemas are in Schuffner's experience sufficient to remove the worms present in light infestations often there is only one worm present. High enemas given with the object of getting at the immature worms higher up in the intestine are not only quite superfluous, but are also often very disturbing to the subject. These worms are better eliminated by anthelmintics. No known substance has all the properties of an ideal anthelmintic. The author discusses and apparently recommends gentian violet (see also CRAW *this Bulletin* 1943 v 40 618). Danish use of this drug is similar to its use by American workers. Reckoning the life of *Enterobius* as from 37 to 53 days (see above) Schüffner concludes that if eggs appear in less than 37 days after anthelmintic treatment (or adopting LENTZ's (*Zent f Bakt* 1935 v 135 158) estimate of the length of the life history in less than 25 days) the anthelmintic has failed. If eggs appear between 37 and 53 days after treatment the drug may have eliminated the worms present but a new infestation (e.g. a dust borne one) may have occurred. If eggs appear after the 54th day after treatment a new infestation must have occurred even if the drug has eliminated all the worms originally present.

Known anthelmintics however must not be expected to give a permanent cure because dust borne infestation is so difficult to control. The author deprecates the use of aperients, which are he thinks, practically never justified. For prophylaxis against finger infection Schüffner recommends increased cleanliness of the hands and washing of the anal region immediately after rising in the morning. This gets rid of eggs before the daytime clothes are put on and the child remains all day in a personal environment more or less free from eggs. Washing after each stool does some good but does nothing directly against the worm. The practice of it is based on the faulty observation that eggs are laid in the intestine and are taken up only from the stool. Schüffner and Swellengrebel found, on the contrary, that eggs are laid only very exceptionally in the intestine.

The wearing of closely-fitting bathing drawers at night is a useful means of prevention of soiling of the hands although eggs, as LENTZE [this *Bulletin* 1938 v 33 121] showed can easily pass through the most closely woven materials. The drawers prevent however the picking up of eggs by scratching and this justifies their use they can convert an active into a latent enterobiasis and they hinder distribution of eggs in the bed and thus prevent dust borne infestation under the bedclothes. Loose night clothes help this kind of infestation.

The precautions so far mentioned may practically close the finger-mouth route of infection, but they only partly restrict dust-borne infection which is especially important at night in bed. KOCH LENTZE and others think that *Enterobius* ceases to migrate out from the anus after midnight, so that a second washing of the anal region after midnight may do good this is, however troublesome for the mother and may for that reason alone, not be justified. Another measure is to close the anus with suppositories, ointments etc. This together with the wash immediately after rising in the morning will almost completely prevent dust-borne infection.

The author thinks that many textbook measures are unnecessary they may also lead to threadworm neurosis. Among these he includes treatment of the members of the family suffering from latent enterobiasis, daily changes of bedclothes and underclothes and sterilization of these keeping the nails short, change of diet stool examinations, high enemas and purges. Dust-borne infection cannot be entirely eliminated, so that it is useless to aim at permanent cure by such strict rules. The author is discussing enterobiasis in Amsterdam, where he says that 100 per cent. of children are infested. When dust-borne infection is not a risk, the author recommends the simple measures given above, because in 5 to 7 weeks the worms will naturally die out. *G. Lapege*

GAASE, A. Ueber die Verwendbarkeit der Komplementbindungsreaktion zum Nachweis der Trichinose. [On the Value of the Complement Fixation Reaction for the Diagnosis of Trichinosis.] *Munch. med. Woch.* 1944 Aug 25 v 91 Nos 33/34 440-41 [14 refs]

The occurrence of a localized outbreak of trichinosis in Germany in 1943 enabled the author to test further the value of the complement-fixation reaction tested by him and others in earlier work. The illness was not severe and *Trichinella* could not be found by meat inspection. The symptoms were more subjective than objective. Within seven weeks the sera of 110 members of the Wehrmacht were sent to Gaase to be tested for trichinosis. Of these 82 (74.5 per cent) were feebly or strongly positive. This percentage of positives seemed to be low but only one sample of 17 out of the 28 negative sera was sent for examination, so that probability of a positive reaction was not great. It was, therefore, all the more striking that in some subjects the reaction was positive shortly after the appearance of the symptoms [the author does not say how long after]. The limited amount of antigen available prevented the use of daily tests to detect the earliest time when positive reactions appeared, but it can be said that the number of positives would have been higher if this point could have been systematically investigated. The value of the complement fixation reaction for the diagnosis of early cases of light *Trichinella* infections was, however demonstrated. In three subjects the reaction was positive or lightly positive on the second day, which is an earlier date than that observed by Gaase in experiments on animals. By the seventh day the number of positives reached 13 the first strongly positive reaction occurring on the fourth day. The author does not however claim any finality for these figures. He used an antigen prepared from swine.

Eosinophilia is an almost constant symptom of trichiniasis but the degree of it does not indicate the degree of the infestation nor does the degree of prevention of haemolysis in the complement fixation reaction indicate the severity of the *Trichinella* infestation. For these reasons the author enquired whether there is any relationship between the eosinophilia and the antibody content of the subject's blood. No such relationship could be found. In most subjects with a strongly positive complement fixation reaction the number of eosinophils was markedly increased but some giving lightly positive reactions had 30 to 40 per cent of eosinophils and conversely others giving strongly positive reactions had 0 to 7 per cent of eosinophils. There is little evidence to decide whether the eosinophilia or the complement-fixation reaction is the more reliable for early diagnosis. Experimental work on animals has enabled the author to demonstrate by means of the complement fixation reaction the presence of a *Trichinella* toxin in the brain [see this *Bulletin* 1945 v 42 481 and the literature there quoted].

The successful use of the complement-fixation reaction for the detection of light infestations of man with *Trichinella* suggests that similar light infestations occur in animals. This consideration together with the fact that outbreaks of trichiniasis occur in areas in which careful inspection of meat for *Trichinella* has failed to detect it seems to justify the supplementing of meat inspection with complement fixation reactions done upon the swine. G. Lapage

DEFICIENCY DISEASES.

GILLMAN T & GILLMAN J. Hepatic Damage in Infantile Pellagra and its Response to Vitamin, Liver and Dried Stomach Therapy as determined by Repeated Liver Biopsies. *J Amer Med Ass* 1945 Sept 1 v 129 No 1 12-19 8 figs. [Refs in footnotes.]

In this paper the authors describe in detail the damage found in liver biopsy specimens (taken according to a modification of the technique of Iversen and Robohn [see this *Bulletin* 1945 v 42 1046]) from African children suffering from the type of infantile pellagra which is so severe that 50 per cent of them die though treated with vitamins and a satisfactory diet. The condition found and the clinical signs together with details of the authors' new and successful treatment with a dried stomach preparation are referred to in previous papers abstracted in this *Bulletin* 1944 v 41 1057 1945 v 42, 748 1946 v 43 9.

The present communication is based on a study of 20 livers. From the pathological point of view these fall into three categories. In the first there is enormous accumulation of fat in the liver cells in the form of single large pale-staining globules filling the entire cell. In the second (less serious) form almost all cells contain multiple coarse droplets of fat. In the third the cells contained dust-like particles of fat.

The authors discuss the results of treatment again emphasizing the value of dried stomach, even in the restricted amounts they were able to give. They think that the presence of large amounts of fat in the liver and in the stools though the diet of the patients had previously consisted largely of carbohydrate, and though there was little fat elsewhere indicates that carbohydrate is converted in the body to fat but that utilization of the fat is deficient and that it is excreted into the bowel or deposited in the liver cells. Vitamin treatment may not only be useless it may actually be harmful and it is known that large doses of nicotinamide produce fatty infiltration in the livers of rats. Other workers have noted the beneficial action of liver therapy in pellagra but in

comparison with the authors' results with dried stomach, the action of liver is slow and incomplete. They stress again their opinion that dietary imbalance may initiate the disease, producing secondary changes which are not susceptible of cure by administration of vitamins.

The African, in the Johannesburg area from which the authors write, exists in poor economic conditions and his liver is subject to repeated insults of this kind. It is likely that the known high incidence of cirrhosis and of primary hepatic carcinoma are due in no small measure to this chronic malnutrition.

Charles W. Wilcocks.

SPRUE.

MAEGRAITH B. G. ADAMS A. R. D. HAVARD R. E. KING J. D. & MILLET R. F. Carbohydrate Absorption in Sprue. *Lancet* 1945 Nov 17 635 2 figs.

In the course of experimental observations on cases of sprue the authors investigated the absorption of glucose and fructose—the former is absorbed from the small intestine mainly after phosphorylation "the process of introducing the trivalent PO group into an organic molecule" (*Dorland's Med. Dict.*) while fructose is absorbed chiefly by simple diffusion through the intestinal mucous membrane.

After each patient had taken 100 gm. of sucrose by mouth the glucose and fructose levels in the blood were estimated every half-hour for 2½ hours. In the active cases of sprue the glucose curve was flat—the maximum rise seldom exceeding 20 mgm. per 100 cc. above the fasting level—the absorption was "of the same order as that of fructose." The fructose absorption curve was always within normal limits. Hence in these cases of active sprue the absorption of glucose was much reduced while that of fructose was unaffected. The reduction of glucose absorption is considered to be due to failure of phosphorylation in the small intestine.

Certain substances are known to be able to inhibit phosphorylation in the small intestine and magnesium, *in vitro* plays an important part in phosphorylation. The authors therefore estimated the plasma levels of Ca and Mg in their patients—the Ca levels showed little difference from the normal—the Mg level was low in two patients (0.75 mgm. and 1.2 mgm. per 100 cc., respectively) who were acutely ill and had tetany at the time. In these two patients no direct relationship between the recovery of the carbohydrate absorption and the return of the Mg levels to normal was observed. In other acute cases without tetany a low Mg level was not found. J. F. Corson.

SINGH, B. Fatty Diarrhoea. A Report on 26 Cases. *Indian Med. Gaz.* 1945 Aug. 80 No 8, 388-90.

The patients, chiefly non-vegetarian Muslims, were admitted to a malnutrition ward in an Indian military hospital after periods ranging from 4 to 36 months (the majority within one year) in the forward areas.

The severity of their complaints could be classified into severe, moderately severe and mild. The manifestations essentially consisted of looseness of the bowel (3 to 13 motions in 24 hours), griping pains, vomiting and retching after meals, weakness and wasting, and in a few cases, "feverishness." The stools were pale, copious, of porridge-like consistency and slightly frothy, and contained 50 per cent. of fat, the ratio of split to unsplit fat being about normal.

All the men complained of soreness of the tongue at some time during their stay in hospital. Their red cell counts and haemoglobin content were not grossly abnormal in 9 cases where a fractional test meal was done it revealed hypoauidity or achlorhydria.

The treatment included attention to diet and administration of drugs including dilute hydrochloric acid, nicotinic acid and the sulphanilamide drugs the latter controlled the diarrhoea while they were being taken but it recurred on their cessation if the general condition of the patient had not materially improved. Small repeated blood transfusions were given in a few cases without obvious benefit.

The author attributes the condition to restriction in food intake added to debilitation consequent on dysentery, a vicious circle thus being set up. The sulphonamides were of benefit in breaking the circle and restoring a more normal equilibrium from the sprue like state (para-sprue) into which the cases had declined.

HERNÁNDEZ MORALES I Gastroscopic and Rectosigmoidoscopic Observations in Tropical Sprue *Puerto Rico J Pub Health & Trop Med* 1944 Dec. 1 20 No 2 257-67 [Refs in footnotes] [Spanish version] A R D Adams

Sixty-one gastroscopic examinations were performed on 36 sprue patients during the acute diarrhoeic stage and after liver extract treatment had been given for varying periods. In 55 per cent. atrophic changes were observed in the gastric mucosa. Practically all showed acute glossitis with absence of the papillae though following liver treatment the tongue showed great improvement. Sixteen were examined after treatment and in 10 the appearance of the gastric mucosa was restored to normal.

Recto-sigmoidoscopic examinations undertaken during the acute diarrhoeic stages revealed several types of lesions such as atrophic patches oedema friability purpuric spots and superficial inflammation.

Gastroscopic examination in sprue is the only available method of studying the changes in the gastric mucosa in this disease. It is once more stated in confirmation of the views of OLLEROS (*Puerto Rico J Pub Health & Trop Med* 1938 v 13 503) that the atrophy of the gastric mucosa is more intensive in pernicious anaemia than in sprue.

RODRIGUEZ MOLINA R. Sprue in Puerto Rico—Ten Years Later *Puerto Rico J Pub Health & Trop Med* 1943 Mar v 18 No 3 314-40. [Spanish version 341-63.] P Manson Bahr

For the purposes of this study the sprue syndrome is held to be a chronic deficiency state characterized by its insidious onset chronicity of symptoms, progressive development of gastro-intestinal disturbances—mainly dyspepsia, soreness of the tongue and mouth meteorism and diarrhoea. The stools are usually liquid foamy greyish foul smelling voluminous and fatty. Stomatoglossitis atrophic gastritis and recto-sigmoiditis are important findings. A macrocytic hyperchromic type of anaemia with a megaloblastic marrow accompanies about 90 per cent. of the cases. Loss of weight occurs in the same percentage of cases fever in about 40 per cent.

The symptoms of sprue may appear and become fully developed in the course of a few weeks but more usually a few months as the chronicity of symptoms is typical. This symptom complex may continue if untreated for several years before death ensues. Relapses are common, but spontaneous remission of gastrointestinal symptoms or of the anaemia are rare.

The rapid loss of weight and strength is associated with intestinal hypermotility with resulting malabsorption, and chronic and progressive starvation. Derangement of the metabolism of fats, carbohydrates and proteins is closely related to the failure of the absorptive intestinal function, and is believed to be intimately linked with the clinical picture of the syndrome.

This deficiency state in sprue is amenable to replacement therapy and symptoms can be cured by liver extract. The group studied comprised 51 males and 49 females, ranging from 12 to 78 years of age the mean age for the group being 40.14 years. There were 87 white and 13 coloured individuals among the latter were two full blooded negroes the others being mulattoes. Ninety-eight persons were natives of Porto Rico. With few exceptions the individuals were indigent and, when first examined, presented the fully developed picture of the sprue syndrome. The liver extract employed for intramuscular injection was prepared according to instructions given by W. B. CASTLE. This is a crude unconcentrated product from 343 Liver Powder Lilly and its efficacy for sprue and other macrocytic anaemias had been demonstrated. One cc. of this extract was equivalent to about 5 gm. of fresh liver. In the out-patient department it was given intramuscularly in doses of 5 to 10 cc. usually 5 cc. three times a week. Injections of 5, 8 and 10 cc. were often given daily in the wards. One individual received as much as 20 cc. intravenously daily. Whenever possible, reticulocytes were counted daily during the first two weeks of liver therapy. Wintrobe's haematocrit was employed to determine the volume of packed cells and a Newcomer Klett haemoglobinometer to estimate the haemoglobin in grammes and percentages. The diet prescribed, that of Ashford, was of low residue, high protein, low fat and low carbohydrate which assured assimilation even in presence of diarrhoea. In practice it included certain Island carbohydrate foods such as plantains, bananas *yandias* (a tuber similar to potato). The diets supplied from 1,500 to 2,000 calories per day.

Of the drugs taken orally the chief was a digestant of hydrochloric acid and pepsin and a small amount of strychnine. Another preparation contained tincture of opium prepared chalk and bismuth subcarbonate used for stubborn diarrhoea.

A table has been compiled of the number of deaths from sprue per 100,000 of population in Porto Rico during the decennial period 1928 to 1938. For the purposes of comparison deaths from other anaemias are also shown. In 1928 there were reported 88 deaths from sprue with a rate of 5.9 per 100,000. In 1938 the total number of deaths reached 103 and the rate 5.6 per 100,000. In white individuals the age groups showing the greatest number affected were 20-29 for females 20-29 and 40-49 for males. Twenty-six white males or one-half of the male group were affected between the ages of 20 and 50. There were 11 white women in the 20-29 group a higher number than in any other. This is significant as indicating that sprue attacked women most often during the period when pregnancy was most likely to occur and that its onset occurred not during pregnancy but after delivery. In the coloured group the largest number of females (3) fell in the 20-29 group of the 6 males there were two in each of the three groups between ages 20 and 50.

A total of 75 white and coloured individuals were discharged as improved and did not return during the ten-year period 1931-1941. The average duration of treatment was three years, with a range of one month to ten years, and the average hospital sojourn for 27 cases was 40 days.

The number of relapses was generally less in patients below 40 years of age. Upper respiratory infections were responsible for the greatest number of relapses next in order were dietary indiscretions. Cessation of liver therapy was also a cause.

The earliest indication of improvement under liver therapy was rapid and progressive disappearance of the lingual and buccal lesions accompanied by change in the appearance of mouth lesions. On diet treatment alone however this process was delayed for several weeks nor were all the papillae completely regenerated. The return of the long lost appetite was taken as an early indication of improvement. Relief of gastrointestinal symptoms was not apparent until a later date. It is believed that improvement was more rapid from liver and diet than with liver alone. Under combined liver and diet therapy the number of bowel movements might diminish as early as the second or third week. It was observed that any indiscretion in the diet even in those who were symptom free always resulted in a change in the appearance and frequency of the stools.

A rise in reticulocytes may be taken to mark the earliest indication of blood regeneration following liver therapy. The peak of this increase usually occurred from the fifth to twelfth day. When the red cells were more than three million the reticulocyte count was rarely higher than 10 per cent. As a rule the proportion of reticulocytes became normal (1 to 2 per cent) by the end of the second week. In general the reticulocyte peaks were lower in sprue than in pernicious anaemia. Changes in the morphology of the red cells such as anisocytosis and poikilocytosis were greatly diminished during the first few weeks of treatment but might persist for months particularly when macrocytosis was present.

In about 50 per cent of cases the mean corpuscular volume rose shortly after administration of liver extract as the amount of cells and their packed volume increased.

The leucocyte count if low usually returned to normal between the fourth and fifth weeks of treatment and the differential count also returned to normal. Macrocytosis of leucocytes disappeared promptly in the majority of cases. Low platelet counts returned to normal but not before the third or fourth weeks of treatment.

The amount of liver extract required to maintain a person with a high threshold requirement in good health once a full remission of symptoms had occurred varied widely with different individuals. The erythrocyte and haemoglobin responded rapidly but normal or subnormal levels were maintained for longer periods in individuals below forty years than in those over this age. In the older age groups clinical improvement with disappearance of gastrointestinal symptoms was frequently observed in association with subnormal blood levels.

The opportunity for observing permanent cures in sprue is lacking. It is known that of the 75 individuals discharged as improved, 65 have apparently remained well after five years without treatment.

Liver extract was given to one individual daily by the intravenous route in 10 and 20 cc. doses. No reaction, save pyrexia of 103°F resulted, but clinical and haematological improvement was no more effective nor did it appear any sooner than when liver was administered intramuscularly.

RODRIGUEZ MOLINA R. Sprue in Puerto Rico. A Clinical Study of 100 Cases. *Puerto Rico J Pub Health & Trop Med* 1941 Dec v 17 No 2, 134-51 2 figs. [Spanish version 152-68]

HAEMATOLOGY

BERG W. N. Blood Cell Counts and their Statistical Interpretation. *Amer Rev Tuberculosis* 1945 Sept. v 52, No. 3 179-220 12 charts. [28 refs.]

The main purpose of this very heavy and careful piece of work, which was undertaken for the Committee on Evaluation of Laboratory Procedures, is to describe the statistical aspects of blood cell counting so that any worker can make his own tests of significance by reading the tables provided. Taking as an example the red cell count the author first shows the variability that may occur by chance in making repeated counts of a single dilution of blood. For instance if 1 000 correct counts were made each on 80 squares, and the mean number of red cells were 300 the individual counts would vary between 248 and 352. This variability is due to chance or purely accidental variations in the way the red cells stream across the squares in the chamber. The majority of the counts would lie in a narrower range two-thirds approximately being between 283 and 317 but wider deviations will inevitably occur with some frequency. In practice this variation will be increased by variations in chamber size and in dilution pipettes. Thus the range of observed counts round the mean of 300 will be increased under normal conditions of careful routine from the 248 to 352 (above) to 224 to 378 two-thirds approximately lying between 275 and 325 (above). The author briefly tabulates the frequencies with which counts would be expected to occur in this way round mean values from 200 to 800 and such statistical expectations have been found to be in accordance with observations.

The first problem arising then is to decide what information is obtainable from a single red cell count. Given, for instance a count of 464 on 80 squares, this result could come from a patient with only 372 or as many as 600 cells though most infrequently in either case. It might well arise from a patient with a real count lying anywhere between 400 and 540 a wide range. The table provided shows the possible limits for different observed counts. The second problem concerns the method to adopt in determining that a single chamber count has been made correctly. One such method is to count the cells separately in each of five groups of sixteen squares note the largest difference that occurs between any two of these five totals and from the table provided see whether such a difference is likely or unlikely to have occurred by chance. If the difference is unlikely error should be suspected. A second method is to compare the actual with the theoretical Poisson distribution, but this is laborious in practice.

The third problem is to determine how large a difference between two consecutive red cell counts on the same blood may be due to random sampling. A table of ranges is provided to show the extent to which two such readings may be expected to vary by chance. Alternatively from another table the ratio of the difference between the two counts to the standard deviation may be calculated. If the difference is greater than three times the standard deviation the probability that both counts were correctly obtained on the same blood is very small. Using this method, the author gives clear examples of its application in three situations—(a) counts on the same dilution (b) counts of different dilutions of the same puncture (c) counts derived from two punctures.

The fourth problem is whether two counts are better than one. If the first count happens to be close to the true value chance will place the second count further away making their mean a poorer estimate than the first count alone. Conversely if the first count is far from the truth chance will place the second count nearer and the mean will in this case give a better estimate. Since the investigator cannot tell which situation he is facing, the mean of two counts

cannot be depended upon to furnish a better estimate than either one alone. For practically all other purposes two counts are better than one.

A similar treatment and discussion is given to white cell counts and the neutrophil count the latter being applicable to other differential counts so long as they exceed 5 per cent of the total count. A table is given for estimating the amount of variation that may occur by chance for differential counts in which the observed percentage is less than 5.

[It is not possible in an abstract to reproduce the tables and explanatory matter in this paper which should be consulted in the original.]

ENGLISH R B Sickleaemia occurring in Africans in Northern Rhodesia. *South African Med J* 1945 Nov 24 v 19 No 22 431

Sickleaemia is present in 17.52 per cent of African males employed on the copper belt of Northern Rhodesia. No significant difference in the incidence among healthy and unhealthy subjects is noted.

ROBINSON G A Rapid Method for detecting the Sickle Cell Trait *Trans Roy Soc Trop Med & Hyg* 1945 Dec v 39 No 3 264

The ferment broth used by NEUDA and ROSEN [this *Bulletin* 1945 v 42 825] in their rapid method for diagnosing sickle-cell disease is really a mixed culture of intestinal organisms. The author has used broth cultures of various bacteria—*Pseudomonas fluorescens* *Bact coli* *Staph aureus* *B subtilis*—for the rapid production of sickling of the erythrocytes. The presence of living bacteria is necessary as heating the cultures at 60°C for 1 hour filtering through Seitz Disk EK/3 or Pasteur-Chamberland Candle L3 or killing the bacteria with alcohol produces inactivity while suspensions from an agar culture are active without further incubation. *Method*—A drop of a 24- or 48-hour-old culture previously tested for its activity against known sickling corpuscles is placed on a slide and a smaller drop of finger blood mixed with it covered with a cover glass and examined under the microscope. In cases with the trait or with active sickle cell anaemia sickling of the corpuscles begins to show in from 1 to 5 minutes in most cases 70 to 90 per cent of the corpuscles being sickled in 15 minutes.

J F Corson.

WINSOR, T & BURCH G E Sickle Cell Anemia, "A Great Masquerader" easily recognizable with Routine Use of Diagnostic Parameter *J Amer Med Ass* 1945 Nov 17 v 129 No 12 793-6 4 charts.

Since sickle cell anaemia is such a great imitator and because it may remain so subtle it is necessary as a routine to study the blood for sickle cell anaemia in all negro patients. This can conveniently be done by the routine diagnostic use of the parameter [described by WINSOR & BURCH see this *Bulletin* 1945 v 42 484] such a search in 512 consecutive negro patients showed 27 (4.4 per cent) to have sickle cell anaemia. Two methods may be used in performing the test one employing CO₂ (diagnostic parameter Δ_1) and the other venous stasis (diagnostic parameter Δ_2) to produce retardation of the rate of the erythrocyte sedimentation.

In the second method a sphygmomanometer cuff is applied to the arm and a pressure between the systolic and diastolic blood pressure is sustained for 6 minutes after which 10 cc. of venous blood are withdrawn into a tube containing either citrate or oxalate crystals. A portion of this blood is then immediately placed in a Wintrobe sedimentation tube and the sedimentation rate

[March 1946]

determined. The remaining portion of the blood is adequately aerated until it is bright red, by rotation at 2-minute intervals for 15 minutes in an Erlenmeyer flask, after which its sedimentation rate is determined. The diagnostic parameter Δ_2 is indicative of sickle cell anaemia when the difference between the sedimentation rates (uncorrected) is greater than 20 mm. per hour. If the difference is less than 20 mm. per hour the chances are 10 000 to 1 against sickle cell anaemia and if the difference is greater than 20 mm. per hour the chances are 93 in 100 that the patient has sickle cell anaemia.

In the first method 5 to 10 cc. of venous blood are withdrawn into a tube containing citrate or oxalate crystals. A few cc. of this blood are then transferred to a rubber-stoppered Erlenmeyer flask into which pure CO_2 is introduced, and the flask is agitated at 2 minute intervals for 15 minutes or until the blood becomes dark blue. A few cc. of the original blood are similarly treated in an open flask and aerated for 15 minutes or until the blood becomes bright red. The sedimentation rates of the two samples are then compared immediately in a Wintrobe tube and a difference greater than 27 mm. per hour between the rates is indicative of sickle cell anaemia.

In the study of 175 control patients with various diseases, including many types of anaemia, the average Δ_2 parameter was 5.3 mm. per hour the extremes being 1 and 18 mm. while the average for 34 patients with sickle cell anaemia was 41.4 mm. the extremes being 29 and 65 mm. per hour. The average Δ_1 parameter for 437 control patients was 5.5 mm. per hour. The extremes being 0 and 24 mm. per hour while the average for 73 patients with sickle cell anaemia was 53.5 mm. the extremes being 29 and 77 mm. per hour. Neither method gave a single false response. Sicklaemia that is the sickle cell trait without anaemia was not included in the series. A high concentration of CO_2 is necessary for a satisfactory result and the gas used to saturate the blood with CO_2 in the second method should contain not less than 85 per cent. CO_2 .

Experiments showed that the more severe the anaemia the greater was the tendency for the parameter to deviate from the normal. Significant differences in the haematocrit determinations of bloods treated with CO_2 and air occurred in patients with sickle cell anaemia. The increase in the haematocrit readings of patients suffering from sickle cell anaemia averaged 50.4 per cent. the extremes being 40 to 70 per cent following treatment with CO_2 whereas in control patients the increase averaged 10.9 per cent only with extremes of 4.3 and 21.4 per cent. Unless the effect of CO_2 on the haematocrit reading is taken into consideration, grave errors may arise in the determination of the an corpuscular volume and the mean corpuscular haemoglobin concentration in haematological studies of patients suffering from sickle cell anaemia, as careless collecting of blood may involve venous stasis.

F. Alvingqvist

VENOMS AND ANTIVENENES.

ROY NAV MED BULL. 1945 No. 17 40-46 3 pls. (1 folding) Poisonous Snakes.

This is a concentrated account in simple language of the systematic position, habits and venoms of poisonous snakes of the world. Some of the statements made might be challenged, but on the whole the information supplied is not highly inaccurate. It is incorrect to state that Many (vipera) have a dark inverted V on the back of the head. Again, the general statement that venom is "ejected through a canal in the fang" refers only to the Viperidae there is no mention of the grooved fangs of the Elapidae. Sound advice is

given on first-aid treatment of snake bite with the exception of the recommendation that suction by the mouth should be carried out. There are several misprints in the table. For instance the tiger snake is *Notechis scutatus* the copperhead is *Denisonia superba* the moccasin is *Ancistrodon piscivorus* the spitting African cobra is *Naja nigricollis*. The statement in the table that *Naja nigricollis* is not very common is incorrect it is of course one of the commonest poisonous snakes in West Africa. The drawings accompanying this article would have been better omitted.

B G Macgrath

FREEDBERG A S & RISEMAN J E F Cobra Venom in the Treatment of Angina Pectoris. *New England J of Med* 1945 Oct 18 v 233 No 16 462-6 4 figs. [13 refs]

A contribution of the highest interest. Cobra venom has been tried for relief of pain in many conditions—cancer, tabes, leprosy, neuralgia and others—and benefit has been noted but always judged by the clinical history only, never objectively evaluated. It has been difficult to decide how much was due to the drug and how far the benefit was purely psychological because the use of inert placebos often gave relief. Among the cases on record in the literature are 14 of angina pectoris.

The authors' study is based on 12 cases of angina pectoris from coronary arteriosclerosis, existent for periods ranging from 2 months to 7 years. The amount of work necessary under standardized conditions to bring on the pain was gauged by RISEMAN and STERN's method, their standard exercise tolerance test. The patients were relegated to one of three groups. Group I reacting well to nitroglycerin and able under its influence to do double the work possible without the drug (4 patients). Group II able to do 50 per cent. more work after nitroglycerin (3). Group III giving no response to nitroglycerin or other usual methods of treatment (5). Seven out of the 12, four of them among the five of Group III, showed an improvement clinically and in standard exercise tolerance of the injection of cobra venom. The dosage at first was 1-2 cc. (10-20 mouse units, i.e. the m.l.d. for a 20 gm. mouse) daily injected into the deltoid for 3-7 days but the best dosage was found to be 1 cc. (10 mouse units) three times the first day then once daily for 7 days. The injections caused local pain but not severe enough to interrupt the course. Relief might last for some 5-6 weeks or for a few days only after the course was completed but the pain then returned and subsequent courses were less beneficial and although the treatment might be continued, the pain would return and the standardized exercise tolerance fall to the original level. No toxic effects followed from the dosage stated above but one patient who was given twice these doses on the first day suffered from pain in the chest, nausea, vomiting and diarrhoea of such severity as to call for cessation of the treatment. The important fact to be noted is that though the pain may be relieved the process underlying it—the pathological cause—remains unchanged and unaffected. The electrocardiogram after exercise is the same as that when no treatment is given. In other words the action of the venom is not to cause dilatation of the coronary vessels. Also as it takes some time—three days on an average—to bring about its effects the venom would be useless for relief of an acute attack.

[The action in relieving pain without affecting the underlying pathological condition is closely analogous to relief of pain by hypnotic suggestion. The abstracter knows of the case of a man suffering from angina pectoris applying to a medically qualified hypnotist for relief. The latter refused, stating that the pain which till then had not been very severe and was controlled by amyl

[March 1946]

nitrite was a warning to him not to hurry or over-exert himself. The patient applied to another hypnotist, not a medical man who gave him relief and he found he could do more such as quickening his pace to catch his morning train without pain. Soon after he hurried thus a little more than usual and died of a heart attack on getting into the railway carriage. The pain had been relieved, but the underlying condition remained, of course unaffected. This does not imply that the venom merely acts psychologically for cobra venom is known to be an analgesic.]

DERMATOLOGY AND FUNGUS DISEASES.

PETERS J T A Clinical Cure of Madura Foot. *Amer J Trop Med* 1945
July 1 25 No. 4 363-5 2 figs [10 refs.]

Madura foot may be caused by any one of 13 species of *Actinomyces* or by any one of 19 species of true fungi (belonging to two classes and eight genera) yet the clinical picture is very similar in all cases this suggests that there is some common denominator.

pathological effects on the tissues of the production of toxins with similar fungus *Monocephium aphrosporum* cases due to *Actinomyces* being much rarer the present case is probably only the third case of Madura foot due to *Actinomyces* in the U.S.A. that has been confirmed by culture of the organism.

The patient a coloured man aged 53 was admitted to the Charity Hospital New Orleans on January 3rd, 1944 with a swollen left foot in which he said he felt occasional moderate pain. The swelling began in 1942, grew larger and discharging sinuses appeared. X-rays showed decalcification of the bones with small punched-out areas at the bases of the 3rd and 4th metatarsals and at the distal end of the 4th metatarsal. What appeared to be *Actinomyces asteroides* (Eppinger-Gasperini) was isolated from the pus of the sinuses.

Treatment.—Penicillin was given for four weeks without effect the total dosage being 1 050 000 units. Sodium propionate was next tried, as dressings containing 20 per cent and as injections of isotonic solutions into the sinuses failed in Madura foot due to *Actinomyces*. Finally sulphadiazine 1 gm. every four hours in the daytime was given for three weeks the urine being always daily and the blood twice a week. The blood levels during the day were always about 8 mgm. per cent. His slight fever disappeared after one week of this treatment. A culture of slow growth was obtained at the end of the three weeks course but the patient refused further treatment as the swelling had much decreased in size and went home. He was advised to take methylsulphadiazine at home but did not do so for reasons of expense and for the same reason did not reappear for six months. His foot was then of normal size the sinuses had all healed, and he was able to do all his work as a farm labourer. He was again seen after six months and was still apparently quite well. The author regards the case as a clinical cure.

J F Corson

CARRIÓN A. L. & KNOTT J Mycetoma by *Monocephium aphrosporum* in St. Croix, Virgin Islands. *Puerto Rico J Pub Health & Trop Med* 1944
Sept. 1 20 No. 1 84-99 22 figs. on 7 pls [Refs. in footnotes.] [Spanish version 100-107]

* The first recognized case of maduramycosis in the Island of St. Croix Virgin Islands is herein studied and reported. The infection was of the white

grain type and its etiologic agent was a Hyphomycete identified as *Mono-sporeum apiospermum* Saccardo 1911. Attention is called to certain morphologic peculiarities of this species which should be taken into consideration for future classifications.

CATANEI A & KERVRAN P. Nouvelle mycose humaine observée au Soudan français [A New Mycosis of Man found in French Soudan] *Arch Inst Pasteur d'Algérie* 1945 Sept v 23 No 3 169-72

The authors identified a case of histoplasmosis of an unusual type at Bamako in the French Sudan. The disease seems to have been localized in the right temporo-maxillary region where it formed a suppurating granulomatous tumour about the size of a hen's egg attached to the ascending ramus of the mandible. An exploratory puncture released about 20 cc. of brownish yellow fluid pus containing the fungus in the form of thick walled oval or rounded bodies having a longer diameter of 6-12 or even 15 microns some of which had an appearance of budding. In culture the fungus developed the characteristic morphology of *Histoplasma capsulatum* in the mycelial form. Reference is not made to the development of the yeast form in culture. The lesion was cured by injecting 1 cc. of lipiodol on two occasions into the cavity left after evacuation of the pus. The culture was infective apparently with little pathogenicity for mice and guinea-pigs but not for rabbits. In the pus of the artificially induced lesions the fungus was found chiefly in the form of small yeasts 3-5 to 4-0 microns in diameter with occasionally a larger form.

[The question whether the *Histoplasma* isolated from African cases of histoplasmosis is a different species from *H. capsulatum* Darling 1906 is worth considering.] *J T Duncan*

HEAT STROKE AND ALLIED CONDITIONS

FARINAUD M E. L'homme et le climat colonial [The Influence of Tropical Climates on Man.] *Méd Trop* Marseilles 1944 May-June-July-Aug v 4 No 3 194-224 1 folding chart

In this review of the effects of tropical climates on man the author has gathered his widely ranging material under two main headings namely the Physical Climatic Complex and the Effect of Tropical Conditions on Organic Functions. The first includes the geographical and meteorological considerations required to explain tropical climatic characteristics and concludes with a series of climatograms for various areas in French Africa and Indo-China. These are built up on plots of mean monthly temperatures against mean monthly relative humidities at the different places. It is shown that the climatograms for most of the French possessions differ markedly from that of a typically temperate region inhabited by a white population and both are removed from the zone of maximum comfort.

In the second part of the review the author attempts to indicate how far the human physiological constants of temperate regions are altered by tropical conditions. Changes in the blood pressure and the concentration and composition of blood in basal metabolic rate and in excretory activity of skin and kidney are briefly discussed, but unfortunately where investigators are named no references are given to their publications.

The conclusion reached is that climatic conditions alone may cause a transitory effect but that so far they have not been shown to have any profound or lasting effect on the physiological functions discussed. This conclusion is also

[March 1948]

applicable to the psychological state of the inhabitant of the tropics. The author observes that the inconveniences and annoyances of colonial life often aggravated by excessive taking of alcohol or drugs form the groundwork on which the neuroathemic and depressive states develop. He also stresses that the effect of the tropics on man can more adequately be considered as a meteoropathological problem, since many of the harmful effects imputed directly to the climate are often the result of pathological changes due to parasitic infections.

A. F. Mawra.

RIMMERSCHMID Gertrud. Some Aspects on the Effect of Solar Radiation and other Factors of the Climatic Environment on Human Being. B Solar Radiation in South Africa and Europe and its Effect on the Human Body. C. The Ultra-Violet Solar Radiation. D The Interrelationship between Quantity and Quality of the Ultra Violet Solar Radiation and its Biological Effects. *South African Med J* 1945 Aug 25 Sept. 8 & 22, v 19 Nos. 16 17 & 18 282-7 308-10 331-4 19 figs. [27 refs.]

(An abstract of the first paper (Part A) was published in this Bulletin 1945, v 42 317.) Part B in this series of papers on the biological effects of solar radiation on man is concerned with the heating effects of visible and infra-red radiation, and part D deals with the intensity and quality of ultra violet radiation, and part C refers to the interrelationship between quantity and quality of the South African Solar Radiation. The data discussed came mostly from the intensities at different times of the day and at different seasons are compared with European observations.

The main factors influencing the total amount of radiation received on a surface is the inclination of the surface and the altitude of the sun, the length of day and degree of cloudiness. Radiation intensity is increased by altitude above sea level. In summer solar radiation is about the same in South Africa as in Europe but is much less in Europe than in South Africa during winter. A calculation is given showing that a ten-minute sunbath in South Africa is accompanied by the absorption of 60-70 Calories.

The chief effect of infra-red radiation is immediate heat erythema accompanied by blistering if there is over-exposure to the far infra red rays. Metabolic changes affecting the blood sugar, sodium and phosphate levels have also been reported. It is concluded that the large amount of solar radiation reaches the earth's surface in South Africa must have physiological and psychological effects on its population.

The intensity of ultra violet radiation is determined by the ozone content of the atmosphere, the turbidity of the air and the thickness of the atmospheric haze. Sky radiation contributes as much as direct solar radiation. The total amount of ultra violet radiation is 5-10 times greater in South Africa than in Europe. There is also a greater proportion of shorter wavelength radiation. The intensity of the lower ultra violet wavelengths is much smaller when the sun is nearer the horizon. The wavelengths between 295 mμ and 320 mμ are biologically most effective.

Ultra violet radiation produces several specific effects due to its actinic action. This action is mainly restricted to wavelengths shorter than 330 mμ. The "relative effectiveness" of a particular wavelength is a function of the biological effectiveness relative to the intensity of radiation at that wavelength. Curves are given showing the relative effectiveness for three different biological effects viz. erythema, bactericidal action and engorgement of transformation. There is a notable increase in effectiveness with higher sun altitude.

The erythema effect would appear to aggravate the skin lesions in chicken pox. This may be important in regard to other infectious diseases in the tropics.

If ergosterol behaves in the human skin as it does *in vitro* a certain antirachitic effect can be expected even if the sun only rises to 15° as in Northern Europe in winter. South Africa obtains considerably more of this ergosterol transforming ultra violet radiation but whether there is too much of it in South Africa's sunshine will not be known until some idea has been formed as to the amount of natural radiation essential to produce an adequate vitamin D supply for adults.

WEINER J S The Regional Distribution of Sweating J Physiology 1945
June 29 v 104 No 1 32-40

This paper describes an attempt to partition sweat loss in three male subjects according to anatomical region. The men were in process of acclimatization to an effective temperature of 94°F . Profuse sweating was induced by continuous step-climbing during the first two hours of exposure the effort being sufficient to raise the rectal temperature to slightly over 102°F . Observations were made during 50-60 minutes following the last work period, when rectal temperature was maximal.

Sweat was collected from a number of small areas on the head, trunk, thighs, legs, feet, arms and hands. Collection was made from three successive groups of ten areas each group including areas from every region in order to reflect at each stage the rate of sweating from the body as a whole. The technique involved initial drying of the skin in the area selected followed immediately by application of a metal ring 7 cm. in diameter and 2 cm. in depth. A well fitting lid prevented loss of sweat. The sweat samples were collected over periods of $2\frac{1}{2}$ minutes during the last 30 seconds of which they were mopped up on previously weighed cotton pledgets.

The difference between the observed overall sweat loss and the combined sweat loss calculated from the regional losses did not exceed ± 8 per cent.

The general conclusions drawn from the experiments are as follows —
(1) There are marked variations in the rates of sweating in different areas of each anatomical region, but approximately 50 per cent of the sweat is lost from the trunk, 25 per cent. from the lower limbs and 25 per cent from the head and upper limbs.

(2) The rate of sweating is greater about the 8th day of acclimatization to heat than on the 3rd day.

(3) The relative intensity of sweating is calculated by dividing the proportion of total sweating contributed by a region by the proportion of total surface represented by that region. The relative intensity is greatest on the trunk and next greatest on the head and varies on other areas according to the individual. Sweating is least on the hands which are affected more by mental than thermal stimuli.

The author discusses how far these differences may be related to number size or activity of the sweat glands. In the absence of experimental evidence he suggests that in some areas e.g. the trunk there may be a greater reserve of unused glands or that individual glands may be on the average larger. [The author might have made the meaning of the term relative intensity clearer by stating that it is calculated by dividing the rate of sweating per unit area of a particular region by the mean overall sweating rate per unit area of the body.]

LADELL, W. S. S. The Effect of Desoxycorticosterone Acetate on the Chloride Content of the Sweat. *J. Physiology* 1945 June 29 v 104 No. 1 Proc. Physiol. Soc. 13P-14P

"Daily intramuscular injections of 10-15 mg. of desoxycorticosterone acetate (DOCA) in man increase body weight and plasma volume and reduce sodium and chloride excretion without changing serum sodium and chloride." Diminished urinary sodium and chloride may be the result of a direct action on the kidney tubules. The author here shows that DOCA has an action on the sweat glands, and by collecting sweat and estimating its chloride in subjects working in a hot room before and during a course of injections of DOCA (10 mgm. doses) found that about 30 per cent less salt was lost in the sweat during the course than before it. The subjects of the experiment gained weight and became oedematous but the effect passed off 72 hours after the last injection.

TROPICAL ULCER.

VINCENT Hyacinthe. Remarques sur l'étiologie la pathogénie et l'agent pathogène "Bacillus fusiformis," de l'ulcère phagédénique. [The Aetiology Pathogeny and Pathogenic Agent, *Bacillus fusiformis* of Phagedenic Ulcer.] *Bull Acad Méd* 1945 v 129 Nos. 30 31 & 32, 545-8

The author was surprised to read in a recent paper by BALOCHET DURAND and RAGE (*Bull Acad Méd* 1945 v 129 533) that there are two types of *Bacillus fusiformis* the non-motile type of Vincent and the motile type of Plant. Both motile and non-motile forms were described by Vincent, who found them together in the same microscopic field as for Plant's bacillus, the latter observed "Miller's bacilli," which were really *Spirillum spirigenum* and from *Spirochaeta vincenti*.

Phagedenic ulcer according to the author is caused by *B. fusiformis* frequently in association with *Sp. vincenti* and other micro-organisms especially staphylococci, and streptococci. When material from an ulcer was injected into the healthy tissues of healthy guinea-pigs and rabbits, no ulcer was produced, but when the injection was made into the previously crushed tissues of these animals which had been kept on a low diet for a few days and especially when other organisms—staphylococci streptococci or *Pseudomonas pyocyanea*—were also injected at the same time typical ulcers were produced. In the tropics ulcers occur in persons who are debilitated by such causes as malnutrition excessive fatigue, or some other infection some races are more susceptible to the infection than others.

The author has successfully treated phagedenic ulcer by first cleaning it with normal saline then drying it and applying a mixture of dry powdered calcium hypochlorite 1 part and dry boric acid powder 9 parts the dressing was renewed every 3 or 4 days. The surrounding skin was painted with tincture of iodine. A suitable diet was prescribed. Healing usually took place in 2 or 3 weeks.

MORANTY J. K. So-called Tropical Ulcer in Angul. *J. Indian Med Ass* 1945 Aug., v 14 No. 11 263-6 & 262, 1 graph & 1 fig. [17 refs]

The occurrence of tropical ulcer in Angul, India, had not been reported before 1942, but in that year and the following one many cases occurred the

infection appeared to have been introduced from Assam by returning soldiers [see also this *Bulletin* 1944 v 41 614 *ibid* 1945 v 42 405] Poverty stricken badly nourished people nearly all men, were chiefly affected.

Smears taken from the ulcers showed abundant diphtheroid bacilli in 4 cases *Bacillus fusiformis* was present without diphtheroids. No facilities for culture were available but several experiments were done on the patients and on pigeons. Ulcer discharge fluid containing diphtheroids was injected intradermally and produced typical ulceration in 7-8 days and the same result was obtained by injecting conjunctival discharge containing diphtheroids if the material injected was previously heated no ulcers were produced. The injection of diphtheroid-containing material into the chest muscles of pigeons caused inflammation and fever and the birds died in 2-5 days.

No immunity apparently developed other ulcers occurred even during convalescence

The leg and the dorsum of the foot were chiefly affected in a few cases the ulcer was on the elbow forearm or thigh but none was seen on the sole or on the face Regional lymphatic glands were not involved. No peripheral neuritis was observed.

Treatment—Many applications were tried but none seemed better than another a simple daily dressing with complete rest of the limb was beneficial The injection of 4 000 units of antidiphtheritic serum daily for 3 days had no apparent effect on the ulcers
J F Corson

SESHADRINATHAN N Tropical Ulcer A Study of One Hundred Cases collected in the City of Madras. *Indian Med Gaz* 1945 July v 80 No 7 344-6.

The author made observations on 100 cases of tropical ulcer in the city of Madras The size of the ulcers varied from $\frac{1}{2}$ in to 2 $\frac{1}{2}$ ins in diameter 73 out of 84 not exceeding 1 in. of 95 ulcers 62 were on the foot 32 on the leg and 1 on the elbow The ulcers were painful and very tender The ages of the patients ranged from 7 years to over 50 years Thirty were weavers by trade and only 4 of these gave a history of trauma as a cause of the ulcer whereas half of the others gave such a history The weavers work with their legs in long pits in which the handlooms are lodged the pits are warm and moist and lined with cow-dung but it is not known whether insects took shelter in the pits Persons of the class of the patients drink little or no milk.

Spirochaetes and fusiform bacilli were present in the ulcers the longer forms of the fusiform bacilli being motile pure cultures of fusiform bacilli were grown on 1 per cent. agar containing 25 per cent. of rabbit blood incubated at 37°C. in an atmosphere of 90 per cent. of hydrogen and 10 per cent. of carbon dioxide but subcultures could not be maintained.

In treatment the best results were obtained with gauze soaked in a warm 5 per cent solution of copper sulphate.

MISCELLANEOUS DISEASES

OGILVIE W H Pitfalls of Tropical Surgery *Lancet* 1945 Nov 10 585-7

The author was a consulting surgeon to the East Africa Force in 1940-42 and to the Middle East Force in 1942-44 and discusses some of the puzzling aspects of surgery which he encountered in Africa he selects as subjects three diseases—amoebiasis malaria, and bilharziasis—and the peculiarities of the African as a patient

Amoebiasis is generally seen by the surgeon in a chronic stage. In two patients an amoebic abscess of the liver simulated gall-stones and two cases of intussusception beginning at an amoebic mass in the caecum were seen, while an amoebic mass in the rectum was mistaken for a carcinoma and a left inguinal colostomy was performed. The author suggests that toxic absorption from the ulcerated bowel may cause subacute arthritis of the synovial type. Operation for haemorrhoids, fistula or anal fissure should not be done within two months after the end of an attack of dysentery and not without preliminary sigmoidoscopy.

Malaria complicates surgical diagnosis and disturbs treatment. post-operative and post-traumatic rises of temperature are almost universal in malarial countries. In abdominal conditions particularly diagnosis is made more difficult.

Bilharziasis was probably responsible for failure to catheterize the ureters on many occasions. several instances of bilateral dilation of the ureters were seen in South African officers.

The African appears to be a biological species distinct from Northern man. the author notes his freedom from arterial disease, duodenal ulcer and parasymphilia even when he adopts town life. The African suffers from acute arthritis and bone disease which appear to be due either to syphilis or yaws. Primary carcinoma of the liver is common among the Bantu races. The author concludes with the sentence. But the standard textbook on tropical surgery has yet to be written.

WILLSON PEPPER, J. K. Impressions of Surgery in West Africa. *Brit Med J* 1945 Dec. 8, 812-14

The author was a surgeon at a hospital in a swampy mosquito-infested region of West Africa for 19 months. his patients were nearly all European troops and he found unexpected differences in the course of surgical diseases and the effect of treatment from what he had previously experienced in temperate climates. staphylococcal infections for example being particularly severe. In this paper he records his general impressions received during that period of work in tropical Africa.

J. F. Corson

CROPPER, C. F. J. Amoebiasis. [Correspondence.] *Brit Med J* 1946 Feb 2, 181

The author disagrees with the opinion of WILLSON PEPPER [above] that the proctoscope may be used instead of the sigmoidoscope with equal results for the diagnosis of amoebic dysentery. In his experience the only visible lesions in a very large percentage of cases are at 5 to 6 in. from the anal margin. He agrees that exhausting wash-outs should not be given before the rectal examination but considers that two or three weak soap or bicarbonate enemata may be given three hours before the examination [with the sigmoidoscope] with advantage.

VISWANATHAN, R. Pulmonary Eosinophilosis. *Indian Med Gaz.* 1945 Aug. v 80 No 8 392-8. [11 refs.]

The condition here dealt with has several synonyms: pseudo-tuberculosis with eosinophilia, benign eosinophilic leukaemia, tropical eosinophilia, eosinophil lung, and the author now suggests another: a variant of the last, namely pulmonary eosinophilosis. He gives a brief review of 85 cases seen during a period of 14 months among nearly 1 000 admissions to hospital for respiratory

troubles. Though they originally came from different Provinces all had been in East Bengal or Assam recently for 3 months or more so a humid climate may play some part in the aetiology. The chief symptom was troublesome but unproductive cough with fever in 51 (60 per cent.) and sometimes asthma like attacks. Physical signs were few basal râles and slight tachycardia, and rhonchi in the asthmatic. Eosinophiles constituted 15 to 80 per cent. of a total leucocyte count of 10 000 to 50 000. X rays showed small dissminated shadows but these are seen in the acute phase only and their absence does not exclude the diagnosis. The blood often gave positive cold agglutination of pneumococci as in some cases of atypical pneumonia. Occasionally there were unusual features such as widespread lymphadenitis pleurisy with effusion palpitation and praeordial pain. Arsenicals bring about a speedy cure though the first injections increase the eosinophilia. The usual method is an initial dose of 0.15 gm. NAB and twice this every 5 days after till symptoms disappear.

As regards causation the author considers previous suggestions of mites (as found by CARTER WEDD and D ABRERA see this *Bulletin* 1945 v 42, 73) he looked for them without success in 6 of his cases atypical pneumonia (because of the high titre cold agglutination test) and the inevitable virus.

BENT M J TURNER, E. L. HOLLOWAY G D & CUFF J R. Nutritional Deficiency as an Etiological Factor in Icterus accompanying Pneumonia in the Negro II. Value of Brewer's Yeast in preventing Icterus in Pneumonia. *Southern Med J* 1945 Nov v 38 No 11 730-33 [12 refs]

From clinical evidence and experiments on dogs the authors [this *Bulletin* 1944 v 41 148] concluded that a high incidence of jaundice in a group of adult negroes was due to a badly balanced diet associated with poor cooking. In the present paper experiments to test the protective action of the vitamin B complex when added to the same deficient diet as was used in the previous experiments are recorded.

Nine dogs (controls) were placed on the restricted diet only and 11 other dogs were given the same diet with the addition of brewer's yeast. After the dogs had been on the diets for 21-49 days pneumonia was induced by the insufflation of pneumococci (Type 1 Robertson strain). Van den Bergh tests were made daily before the insufflation and twice daily afterwards. The dogs were killed and examined one to four days after the insufflation.

None of the 11 dogs on the diet plus yeast developed a positive van den Bergh reaction while all the 9 controls did. All the control dogs lost weight while none of the others did, and 5 of them gained weight the former however rejected more and more of their food as time went on.

Post mortem examination showed that all the 9 controls had pneumonia and extensive fatty changes in the liver the other 11 dogs had less severe pneumonia, 5 of them showed no pathological changes in the liver and only one showed changes comparable with those observed in the controls.

The results support the conclusions reached in the previous observations and experiments.

GENERAL PROTOZOOLOGY

KIRBY H. The Structure of the Common Intestinal Trichomonad of Man. *J Parasitology* 1945 June v 31 No. 3 163-75 27 figs. on 3 pls. [18 refs.]

The author has studied cultures of two strains of trichomonads of the human intestine employing dark-field illumination and films fixed in Hollande's cupric picroformal and impregnated with silver by activated protargol as recommended by BODIAN for nervous tissues and adapted to protozoological technique by COLE and DAY. By the impregnation technique a flattened structure not hitherto described was found at the anterior end of the body. It is termed the pelta. It lies to the right of the blepharoplast-complex and is continued as a filament in the cytoplasm dorsal to the nucleus. A small ellipsoidal parabasal body lying against the anterolateral surface of the nucleus was also demonstrated. In other respects the findings are mainly in agreement with those of WEXICHI: this *Bulletin* 1944 v 41 687-698 particularly with regard to the existence of five anterior flagella four of which, directed forwards, have a common origin in the blepharoplast-complex, while the fifth originates independently from this complex and is directed laterally or posteriorly. The author follows WEXICHI "in his opinion that there is one species that is commonly found in the intestine of man and, in fact, there are grounds for surmising that there is a possibility that all accounts of trichomonads from that situation, except that of *Tritrichomonas faecalis* have actually dealt with the one species." The author considers that the presence of 5 flagella one of which arises independently of the others justifies the use of the generic name *Pentatrichomonas* the intestinal trichomonad of man being denominated *Pentatrichomonas hominis* (Davaine 1860). The paper is illustrated by a series of drawings and microphotographs showing the various structures revealed by the technique employed. C. M. Wenyon.

CALLAHAN, W. P. Jr. The Incidence of Toxoplasmic Infections in the St. Louis Area. *Proc. Soc. Exper. Biol. & Med.* 1945 May v 59 No. 1 68-70.

As cases of toxoplasmosis seemed to be of fairly frequent occurrence in the St. Louis area of U. S. A. the author decided to test sera from apparently healthy individuals by Saben's neutralization method, in which varying dilutions of serum mixed with toxoplasmas are inoculated into the skin of rabbits. Eight fatal cases of toxoplasmosis had been observed in St. Louis since 1940. Two were in adults who suffered from an acute febrile condition associated with a skin rash, resembling the typhus-spotted-fever group of diseases. The other cases were in infants in whom the disease was apparent at birth or commenced soon after. There was widespread involvement of the central nervous system giving rise to generalized convulsions, muscular paralysis and internal hydrocephalus. Cerebral calcification and encephalomyelitis with the formation of many granulomatous lesions were the chief pathological changes. Toxoplasms were present in small aggregates or in pseudocysts and as free organisms in the central nervous system. Of 100 sera tested, 74 were from inhabitants of St. Louis and 26 from persons outside the state of Missouri. Only two of these sera prevented the production of skin necrosis by the toxoplasma injected.

These were from unmarried girls 18 and 21 years of age of the St. Louis area. Neither showed any evidence of present or past illness which might be interpreted as toxoplasmosis

GENERAL ENTOMOLOGY

HADDOW A J The Mosquitoes of Bwamba County, Uganda. III. The Vertical Distribution of Mosquitoes in a Banana Plantation and the Biting Cycle of *Aedes (Stegomyia) simpsoni* Theo *Bull Entom Res* 1945 Nov v 36 Pt 3 297-304 3 figs

The vegetation and climate of the Bwamba area were described in Part I and the activity of the local mosquitoes was dealt with in Part II of this series of papers [see this *Bulletin* 1946 v 43 79 80] The third part is mainly concerned with the biting activities of *Aedes simpsoni* (the vector of human yellow fever in Bwamba) at different vertical levels

Four catching stations were established near a large banana plantation. One was on the ground among heavy undergrowth the other three were on platforms in the trees. The first of these was erected at six feet from the ground among leaves of young plants the next was at 12 feet among leaves of full-grown plants and the highest was at 18 feet in the open air above the tallest plants

The catching of mosquitoes from human bairs at all four stations was done simultaneously and continuously for ten days five of which were hot and bright with cold mornings and the other five warm and cloudy with warm mornings. Catches for each hour from each level were recorded separately

The total catch was 687 mosquitoes belonging to 16 species (counting the mixed *Culex* spp as one). The vertical distribution of all species was as follows: 210 (eleven species) at ground level 182 (nine species) at 6 ft 167 (seven species) at 12 ft. and 128 (six species) at 18 ft. *Aedes simpsoni* accounted for 596 of these as follows: 179 159 141 and 117 at the respective levels. Other species were so scarce that their numbers were inadequate for discussion but it is noted that sylvan species such as *Anopheles implexus* (1) *Aedes apicoargenteus* (1) and *Aedes africanus* (3) were present in the catches though the nearest breeding places of *Aedes apicoargenteus* and *Aedes africanus* were in the forest half a mile away where larvae were abundant in tree holes

By grouping the catches in hourly and four hourly periods it is shown that *Aedes simpsoni* is a strictly diurnal species most active on the warm cloudy days which produced 445 as against 151 for the hot bright days with cold mornings

The principal raiding monkey in Bwamba is *Cercopithecus mitis* *mpangae* Matschie the common red tail or white-nosed guenon. Out of 41 of these monkeys 25 were found to be immune to yellow fever and it is suggested that an infected monkey feeding on the bananas at the 12 ft. level could easily pass on the yellow fever virus to *Aedes simpsoni*;
H S Leeson

ADAM N K A Rapid Field Method for assessing the Spreading Power of Anti-Malarial Oils. *Bull Entom Res* 1945 Nov v 36 Pt 3 269-72

It is essential that an oil used for killing mosquito larvae should spread completely over the surface of the water to be treated. Most natural waters

especially if stagnant, are already covered with a film, either visible or invisible which the spreading oil must push aside. The efficiency of the antimosquito oil therefore, depends to a large extent on its spreading pressure. In the laboratory this can be measured directly in dynes per centimetre (see ADAM *Proc Roy Soc B* 1937 v 122, 134) but it is often important to use a more simple method, and portable apparatus especially in the field.

The method suggested employs a prepared series of liquids of standard spreading pressure. These are either compared with an unknown liquid on a clean surface, or tested against a natural film the substance producing a film with the greater pressure will push back the other film. In the laboratory rapid tests are made with a large glass funnel cleaned and kept clean by water overflowing round the rim from a supply through the stem. The water flow is stopped and a little water tipped out to lower the level just below the rim a drop of one oil is applied to the surface covering it with a film and leaving a lens of about a quarter of an inch in diameter. The second liquid is then added and the effect observed. If necessary talc powder can be shaken on to facilitate observation of movements of the films.

The liquids of choice for the standards may be used alone or as solutions in non-spreading mineral oil (medicinal paraffin). They must not be volatile and they must not be affected by the pH range to be expected in natural waters. The following series are recommended —

Standard Spreading Liquids

	Spreading pressure dynes per cm. 20°C
Methyl or ethyl salicylate	13
Dimethyl or dibutyl phthalate	21
Terpineol, liquid (from B.D.H. Ltd.)	36
Oleyl alcohol (from I.C.I. Dyestuffs Ltd.)	47

Standard Spreading Solutions.

Solvent B.D.H. Liquid paraffin S.G. 0.835-0.850

Terpineol in paraffin		Oleyl Alcohol in paraffin	
cc. Terpineol per 100 cc. sol.	Sp. pressure dynes/cm. 20°C	gm. Oleyl Alcohol per 100 cc. sol.	Sp. pressure dynes/cm. 20°C.

HOERN, D. Nephrosis probably due to Excessive Use of Six-way Insect Repellent. *J. Amer. Med. Ass.* 1945 June 16 v 128 No. 7 513

A white boy aged 3 years was admitted to hospital on 4th August, 1944 acutely ill with generalized oedema. His urine contained pus and albumin but no casts. He improved for a few days then the oedema increased and by September he appeared to be dying. He was given four plasma infusions and two blood transfusions after which he gradually improved and at the time of writing was in fairly good health.

During the whole of the summer an insect repellent called Sta way had been freely applied to his skin tests were made on rabbits and it was found that Sta way was a strong kidney and liver poison

The author concluded that the child had suffered from nephrosis due to the application of Sta way *J F Corson*

LABORATORY PROCEDURES

MERTENS Elizabeth A Simple Technique of Sternal Marrow Biopsy for Spreads and Sections *Amer J Med Sci* 1945 Nov v 210 No 5 630-34 6 figs.

The author describes a method of sternal marrow aspiration which has most of the advantages of both the aspiration and the trephine methods without their disadvantages it resembles the aspiration method but differs in that the blood is allowed to clot and sections can therefore be made

The skin subcutaneous tissues and periosteum having been anaesthetized with 1 per cent. novocain solution a 15 gauge Osgood sternal puncture needle is entered in the mid-sternal line at the level of the upper border of the 3rd costal cartilage. The stylet is removed when the marrow cavity is reached and the needle is then gently pushed on at an angle of 30 to 40 degrees for not more than 7 mm. in an adult or until the resistance of the posterior lamella is felt. A dry 10 cc syringe is then attached and sternal marrow and blood are aspirated to a height of 2-3 mm. in the syringe The tip of the syringe should have a bore equal to that of the needle The syringe is detached and the plunger withdrawn for about 1 cm. and the contents allowed to clot when clotting is complete the plunger is withdrawn with the attached clot which is then put into fresh Zenker's formal solution for fixation Paraffin sections are cut and stained with Azure II Eosin.

To obtain films the needle is withdrawn as far as the anterior lamella the stylet removed and the needle passed again into the marrow cavity in a slightly different direction a second syringe is attached a second specimen aspirated the stylet reinserted and the needle removed. *J F Corson*

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

SICÉ A Role social du médecin colonial en Afrique Française [The Social Function of Colonial Medical Officers in French Africa.] *Méd Trop* Marseilles. 1944 May-June-July-Aug v 4 No 3 163-63

The French language is perhaps the most perfect medium for dignified and persuasive prose and General Sicé is a master of its use. His theme is worthy

situated on the outskirts of the town in the years 1939-1941 the average monthly numbers of patients treated were 850 1,950 3 020 and 3 700 and in the summer of 1941 over 5 000.

Kabul, an old town with a population of 140 000 has many narrow crooked, unpaved streets and houses built of mud. It has however a pipe borne water supply brought from the mountains about 20 miles away. The water is good and is periodically examined, and if an epidemic is threatened, it is chlorinated. The water supply is insufficient for modern needs and the new houses in the suburbs have water tanks which are filled daily. The drainage of surface and waste water is primitive but in the newer parts covered soakage pits in the dry porous soil are satisfactory. The latrines are simple pits.

Some years ago the lay-out of a new town was begun. It was originally planned as a university town with modern construction, sanitation and water supply.

The duties of the health officer include street cleaning supervision of markets slaughter houses and food bazaars bath houses and the drainage of waste water. In addition there are preventive measures against malaria, cholera, smallpox and trachoma, and efforts to obtain greater care of infants and small children. As in some other Mohammedan countries the seclusion of women is a hindrance to medical progress.

Modern Afghanistan strives to keep in touch with Western European science. A Review of Hygiene in the Persian language has been published for some years. In the author's time some Afghan students who had studied in Europe together with some French naturalists in Afghanistan, founded a society for the study of valuable products of the earth—minerals, medicinal plants and medicinal springs. This had the interest and support of the Ministers of Health and Agriculture.

The author describes briefly the chief infectious and non-infectious diseases of the country. *Malaria* benign tertian and subtertian, is widespread.

tan malaria is unknown and there is no record of *blackwater fever*. Little known of anopheline vectors. *Kala azar* is not known to occur but cutaneous leishmaniasis is present and *Phlebotomus* abounds. It is unknown whether canine leishmaniasis exists in the country. *Trachoma* is very common. In Kabul it affects about 13 per cent of the population. *Relapsing fever* of the Persian type, probably tick-borne occurs in the spring and early summer. *Typhus* never in epidemic form is present from January to April, *typhoid* and *paratyphoid* A and B in the late summer autumn and first part of the winter. *Bacillary* and *amoebic dysentery* occur the latter being widespread though amoebic carriers were found among the Germans resident in Kabul, no amoebic dysentery is known there. *Shiga-Kruss Flexner* and *Sonne* types of dysentery bacilli *Salmonella breslau* and *Bact. faecalis alkaligenes* have been isolated. Acute intestinal diseases cause a large part of the high mortality among small children. *Cholera* *smallpox* and *plague* occur sporadically. In 1838 an outbreak of cholera occurred, with 3,291 cases and 1 710 deaths. Nearly half a million persons were vaccinated and there was no outbreak in the following year. *Undulant fever* and *abortus fever* are not known to occur. *Leprosy* is present but its extent is unknown. It is estimated that there are from 1,200 to 3 000 cases in the whole country. It was proposed to form a leper settlement, largely self-supporting about 10 miles from Kabul but the war prevented the carrying out of the plan. Little is known of the prevalence of venereal disease. The author saw only a few cases of syphilis and gonorrhoea in Kabul. Few cases of *dysphtheria* and *scarlet fever* are seen, but *measles* is prevalent and ranks after *smallpox* and *whooping cough* as a fatal disease in children. *Tuberculosis* in Kabul appears to resemble the disease in Europe.

in its incidence and course extrapulmonary tuberculosis appears to be rather common. Various other cosmopolitan diseases occur and call for no special mention.

The author thinks that the high mountain ranges on the eastern side form an epidemiological barrier as well as a geographical one. In its epidemiology Afghanistan resembles the countries on the western side where there are few geographical barriers. The paper contains many references to medical reports of neighbouring countries.

BOOK REVIEWS

ACKERKNECHT E H. Malaria in the Upper Mississippi Valley 1760-1900. *Suppl to the Bull History of Med* 1945 No 4 pp viii + 142 with maps & figs [Bibliography]

The Upper Mississippi Valley is one of those interesting regions from which malaria once very prevalent disappeared long before the introduction of any systematic antimalarial measures and largely before the acquisition of knowledge of its mode of transmission. In this very interesting monograph the author has gathered together a surprisingly large amount of information from records of the early days of the conquest and settlement of the great continental heart of North America when ague was so formidable a menace to health along the rivers which constituted the chief means of communication. From then up to recent times the records have been searched for information bearing on this fascinating epidemiological problem and the search has been fruitful.

The five States included in this area Illinois Missouri Iowa Wisconsin and Minnesota are each described and considered independently. A map of each State is attached. Then the factors which may have contributed to the elimination of the scourge of malaria are discussed in turn and numerous authorities are quoted. The factors considered are population movements steamships railroads and river regulation clearing cultivation and drainage prosperity housing screening food education cattle breeding mosquitoes quinine climate. Clear and concise answers to the innumerable questions raised in inquiries of this nature are hardly to be expected but the author does show that the arrest of population movements was accompanied by a decline of malaria incidence in Missouri Iowa and Wisconsin. Another important factor was the shifting of settlements away from watercourses that resulted from the construction of railroads. Drainage enterprises may have speeded up the decline of malaria in Illinois but elsewhere the decline preceded organized drainage. Better housing and an increase in dairy cattle characterized the period of malaria decline. To quote the author's concluding words it may be well to remember that malaria in the Upper Mississippi Valley was not killed by a single magic bullet the monster was only put in chains the links of which we have tried to study. Each link of the chain is important and the breaking of one link may set free again the evil fiend. But as the author repeatedly states the climate in the Valley is not very favourable for malaria.

Norman White

CASTILLO Roberto Levi. *Los anofelinos de la Republica del Ecuador* Vol. 1 172 pp., numerous figs. maps & pla. 1945 Guayaquil Ecuador Artes Graficas Senefeldor C. A. Ltda.

This is a systematic and adequate description of the *Anopheles* hitherto recorded in the Republic of Ecuador. An introduction details the salient geographical features of the country and the climatic conditions. The equator traverses the north of Ecuador. The three natural geographical regions of the country are: a coastal region between the Pacific Ocean and the western escarpment of the Andes, comprising the provinces of Esmeraldas, Manabi, Guayas, Los Rios and El Oro; a mountainous Andes region comprising the provinces of Carchi, Imbabura, Pichincha, Cotacachi, Tungurahua, Chimborazo, Bolivar, Cañar, Azuay and Loja; and an eastern Amazon region wedged in between Colombia and Peru and the eastern escarpment of the Andes, and comprising the provinces of Napo-Pastaza and Santiago-Zamora. The species of *Anopheles* found in these three regions are: Western coastal region, *A. (Chagasia) bathanus*, *A. pseudopunctipennis lericastilloi*, *A. cisnei*, *A. punctimacula* and *A. apicimacula*; *A. mediopunctatus*, *A. albimanus*, *A. aquasalis* and *A. netoi*; Central Andes region, *A. pseudopunctipennis rivadeneirai* and *A. cisnei*; Eastern Amazon region, *A. boliviensis*.

All these species are fully described and illustrated. *A. albimanus* is the main vector of malaria throughout the coastal provinces where it is very widespread: infection rates of from 3 to 5 per cent. have been recorded. The author believes that Ecuador is the southern limit of distribution of *A. bathanus*: it has never been reported from Peru. Of the two races of *A. pseudopunctipennis* found in Ecuador *A. pseudopunctipennis rivadeneirai* is the chief vector of malaria in the warm highland valleys: it is found in all the provinces of the central Andes region and has been found as high as 2,500 metres. It has a marked preference for human blood. In contrast *A. pseudopunctipennis lericastilloi* exhibits marked zoophilism: it is not found at altitudes above 300 metres. *A. cisnei* is a wild species and is zoophilic: it has been found at altitudes ranging from 88 to 2,100 metres. *A. apicimacula* was found in five of the central Andes provinces: it is zoophilic and is only met in jungle far from human habitations. *A. mediopunctatus* occurs in coastal jungles but is very rare. *A. aquasalis* is the only species found breeding in brackish water in Ecuador: it breeds in crab holes in banks of inlets from the sea in the coastal provinces. *A. (Kertessia) netoi* breeds exclusively in bromeliads in the five coastal provinces. *A. (Kertessia) boliviensis* of similar breeding habits is very abundant in the Amazon provinces of Ecuador. It frequents human dwellings and has a preference for human blood: it is a suspected vector of malaria.

The numerous photographs appended to this small volume are very indifferent and add nothing to its value.

FIDWEGAN Susan (B.Sc. Ph.D.) *Aeari as Agents transmitting Typhus in India, Australasia and the Far East. British Museum (Natural History) Economic Ser. No. 16* 78 pp., 49 figs. (2 maps 1 folding) 1945 London. Printed by Order of the Trustees of the British Museum. [1s. 6d.]

The serious military problem presented by scrub typhus in S.E. Asia and the S.W. Pacific during the war was generally quite unexpected. Few people had any practical experience of the disease and a great demand for information and literature therefore arose. Dr Susan FIDWEGAN's book is intended to make modern knowledge about the vectors of scrub typhus, and of other rickettsial diseases transmitted by mites and ticks, easily accessible to workers in the

field. This sort of information is otherwise almost entirely inaccessible to such workers and the book should be widely welcomed. Clear diagrams and useful keys make identification of the important species possible.

From the strictly entomological point of view the greater part of the contents of this book will probably require little in the way of fundamental modification in the near future though additional sections may be required. But since it went to press there have been many papers dealing with the transmission and ecology of the diseases concerned, which will necessitate considerable modifications in future editions. The end of the war will also permit the inclusion of control measures hitherto kept secret.

A most unfortunate misprint occurs in the table giving the characteristics of the rickettsial diseases. scrub typhus is shown as giving a negative reaction with *Proteus OXA* in the Weil Felix test.

BABLET J. *La fièvre jaune. Diagnostic différentiel clinique et histopathologique. Hépatite amarle.* [Yellow Fever Differential Clinical and Histopathological Diagnosis. Yellow Fever Hepatitis.] Collection de l'Institut Pasteur. 69 pp. 10 text figs. & 6 figs. (4 coloured) on 3 pls. 1945. Paris. Les Éditions Médicales Flammarion.

The title of this work—Yellow Fever—is somewhat misleading for the greater part and indeed the only section of any value is devoted to a reproduction of the author's observations on the histopathology of the disease [see this *Bulletin* 1936 v 33 333 *et seq.*]

After an introduction stressing the importance of viscerotomy for the examination of the liver in all doubtful cases the author gives a brief summary of the principal endemic centres of the disease at the present time. The view is expressed that yellow fever was introduced from the Antilles and America into South America and West Africa. No evidence is adduced in support of this opinion which is opposed to the generally accepted view that yellow fever was introduced into the Western Hemisphere from West Africa. The account of the symptomatology contains descriptions of a few fatal cases of yellow fever to illustrate what is stated to be a typical form of the disease among Europeans during epidemics also two atypical examples in which the diagnosis was established by histological examination of the liver. There are also brief chapters on clinical differential diagnosis and on the various biological examinations which can be used in establishing the nature of the disease.

The main part of the memoir starts with a historical summary of work on the pathological anatomy of yellow fever. Since 1935 the author has been in charge of the histological examination of the livers of all cases of suspected yellow fever from the French Colonies including the Antilles and Guiana in addition to West and Equatorial Africa. As a result of the study of hundreds of cases he has come to the opinion that the histological changes in the liver furnish the best practical method of diagnosis. Two degenerative processes are constantly in evidence fatty degeneration and necrosis of the hepatic cells. Details are given of the best staining methods and the changes are illustrated by an excellent coloured plate.

The differential diagnosis of the conditions producing liver changes that might be compared with those accompanying yellow fever are then described and illustrated. The most important are the intoxication effects of carbon tetrachloride arsenicals chronic hepatitis spirochaetal jaundice etc. An appendix by Françoise BLOCH and M. R. GODIN contains technical details of the methods used for staining paraffin sections of the liver for the histological diagnosis of yellow fever. The bibliography includes for the most part only publications dealing with the pathology of the disease.

This memoir contributes nothing new to our knowledge of yellow fever and its only value lies in the section on the pathological histology of the liver with its excellent illustrations

POLAK, Marius Frans. *Vraagstukken der gele koorts. Epidemiologie en vaccinatie* [Problems of Yellow Fever Epidemiology and Vaccination.] [Thesis for Doctorate of Medicine Univ., Amsterdam, 15 Aug 1945] 183 pp 2 figs (1 map) & 3 charts. [432 refs.] English summary pp. 160-63 1944. Amsterdam NV Noord-Hollandsche Uitgevers Maatschappij

The author of this thesis has made an extended summary of the literature on the subject as his list of 432 references indicates. The book was written in Holland however and few of the papers quoted are dated later than 1940, so that full information was not available to the author on the wartime experience of vaccination in American and British troops and on the epidemic in the Sudan which began late in 1940 and of which only the beginning is here referred to.

The chapters contain information on — Recently acquired knowledge of the epidemiology of yellow fever — an investigation into its spread in Surinam — the modifications in the virus produced by passage in animals — vaccination with attenuated virus — vaccination experiments carried out in Amsterdam with virus 17D — and a comparison between the methods of vaccination with the French neurotropic strain and the American 17D.

Protection tests in Surinam indicate that jungle yellow fever exists there that in the Negroes the men run greater risk of infection than the women, probably because their work takes them more closely into contact with the forest and that in the aboriginal Indians the risks to the sexes are about equal.

Charles Wilcocks.

VASSI, Vittorio [Direttore Inc. dell'Istituto di Parasitologie dell'Università de Roma]. *Terapia clinica delle malattie da zoo-parassiti dell'uomo.* [Clinical Therapy in the Parasitic Diseases of Man.] Prefazione del Prof. Vittorio PETERS. 256 pp 37 figs. 1944. Rome Editrice Nazionale. [L. 335]

In the first part of this book the author discusses the general principles of chemotherapy and describes the chemistry and therapeutic action of arsenicals, antimonial, acridine derivatives and other drugs which have a bearing on the treatment of protozoal infections. In a similar section he deals more briefly with anthelmintics, but gives in considerable detail the procedures he advises in the preparation of the patient and the administration of the drugs. In this section male fern, santonin, chenopodium, carbon tetrachloride and other compounds are described.

The second part of the book is devoted to the various diseases in relation to the treatments available and contains some brief notes on diagnosis. The protozoal diseases include those due to intestinal protozoa and to the blood and tissue parasites. American trypanosomiasis is not included. The helminthic diseases include all the common conditions. In a final section are considered myiasis, scabies and pediculosis.

This book was published early in 1944 and was no doubt written before the liberation of Italy. The author was not, therefore able to consult the most recent work done on some of these subjects by the members of the British and American forces. Nevertheless, one would have expected some reference to the aromatic in leishmaniasis and trypanosomiasis, and a more favourable view of the role of the tapeworm infestation. On the whole

however this is a careful collection of information on most of the known treatments for the conditions with which it deals but it will need considerable modification and amplification in the next edition when the author has had opportunity to assimilate all the work which has recently been done.

Charles Wilcocks

JULIAO Oswaldo Freitas. *Contribuição para o estudo do diagnóstico clinico da lepra nervosa.* [A Study of Nervous Leprosy and its Clinical Diagnosis] [Thesis Fac. of Med. Univ. S. Paulo 15-1 1945] 203 pp. 84 figs. on 28 pls & 12 text figs. 1945 São Paulo Industria Grafica José Magalhães Ltda.

A literal translation of the title of this book would fail to convey the extent of the information which it contains. The author has had unique opportunities for observing and studying nervous diseases in general and the nervous lesions of leprosy in particular and he has made the most of these opportunities with the result that he has produced a book which must surely prove to be the last word in nervous leprosy for a long time. It is not a book to be read through or continuously but all practising leprologists should have a copy for ready reference.

The importance the difficulties and the responsibility of making a diagnosis of nervous leprosy are very great. The veriest tyro cannot fail to diagnose leprosy in its developed stages with disfigurements deformities and mutilations or even earlier in the tubercle form it is in the early stages and above all in the early nerve stages that difficulties arise and they may be great.

No one could be better qualified than the author to pronounce *ex cathedra* on this question. He possesses for his task the dual qualification of being neurologist to the Department of Leprosy Prophylaxis in São Paulo and at the same time a member of the staff of clinical neurologists of the Faculty of Medicine of the São Paulo University.

The author therefore has abundant material at his disposal and for purposes of description he has divided the work into three sections or chapters but from the nature of the subject these must to some extent overlap. At the same time unless some such subdivision were made it would be difficult to avoid confusion. The first chapter is named the *Nervous Manifestations of Leprosy* and treats in detail with exemplary cases to illustrate them of definite or more or less isolated clinical symptoms such as conditions affecting motility of digits or of larger muscular associations of the limbs affections of the cranial nerves changes in the reflexes superficial and deep of the cutaneous vasomotor system of sweating and of sensory and trophic disturbances—cutaneous atrophy ichthyosis scleroderma 'glossy skin' alopecia onychia perforating ulcer of the sole bone resorption etc.

The second chapter is the shortest of the three occupying 30 pages or one fourth the length of the first. This chapter is concerned with the *Clinical Forms of Nervous Leprosy* and is itself divided to describe three groups of cases: the first according to the localization of lesions neuritis monoplegic paraplegic hemiplegic the second according to the predominance of one or other classes or association of symptoms—sensory motor trophic psychic or mixed thirdly according to the course whether acute subacute or chronic and benign stationary or retrogressing. This chapter ends with an account of diagnosis of nervous leprosy by means of biopsy specimens of the suspected nerve. Examination of these rarely reveals bacteria but the histological changes are fairly distinctive and characteristic—attenuation of the myelin sheaths and Wallerian degeneration. This method is of particular importance

or avoided in any settlement in which the known appropriate preventative measures are applied.

The conclusion to which Swellengrebel's work leads is that if there is any argument valid against the introduction of Jewish refugees as settlers in Surinam it is not the argument of undue danger to their health. The climatic conditions *per se* do not contraindicate white settlement and the incidence of disease for a tropical country is low. The point is made however that small communities lead to inbreeding and that attention should be given to this fact.

Readers of this volume will find in it much that may have a bearing on similar problems elsewhere, though many of the conditions in Surinam are not common elsewhere in the tropics.

Charles Wilcocks.

BOBRINSKOY N. KUZNETSOV B. & KUTYAKIN A. [Mammals of USSR.] 440 pp 258 figs 32 pls. & 62 maps. 1944 Moscow. Issued by Government Publishing Office Sovetskaya Nauka. [In Russian with an English Preface.]

This is a useful reference book, compiled to aid any person somewhat familiar with the subject to determine the specific name of any of our mammals and to receive a more or less complete information on the geographical distribution of the mammal on the territory of this country though the information concerning the more remote areas is as yet incomplete.

Keys are given, and for each species there are notes on morphology and biology. The geographical distribution is summarized in 62 maps at the end of the volume. There are many line drawings of skull and tooth structure and 32 half-tone plates of most attractive pastel and wash drawings (in monochrome) of the animals in their natural surroundings.

To the epidemiologist the long section on the Rodentia will be of most value.

Charles Wilcocks.

LEAGUE OF NATIONS. Report on the Work of the League during the War submitted to the Assembly by the Acting Secretary-General. Ser. L. O. N. P. General 1945 2. 167 pp. Geneva. 1945 Oct. [Allen & Unwin Ltd. 40 Museum Street London W.C.1.] [2s.] [Review appears also in *Bulletin of Hygiene*.]

The old League of Nations will shortly be replaced by the new United Nations Organisation and the terms of transfer are now under discussion. This report by the Acting Secretary-General, prepared for submission to the League of Nations Assembly which will be convened in 1946 presumably for the last time, describes the work done by the various League Committees and by the Secretariat since 1940 and shows how League organs have adapted themselves to war conditions and how in spite of the breakdown of the political system of the Covenant the non-political technical services have not only survived, but have been performing vital and most valuable duties throughout the war period.

The introductory pages refer to the potential usefulness of the League's activities as a basis for post-war reconstruction and to the problems connected with their transfer to the new United Nations Organisation. An assessment of the value of the League's first "great experiment" in world organization is also attempted.

Chapter 1 of the report deals with the work of the Economic Financial and Transit Department of the League—made easier by the transfer in 1940 of a part of its staff to the United States where a base was set up for observation and intensive research on questions relating to the reconstruction of the world's economic life after the war.

The social and humanitarian activities of the League are then reviewed in Chapter 2 and here an account is given of the work of the Health Organisation which with a staff reduced by 1940 to two doctors—the Officer in charge of the Health Section and the Chief of the Epidemiological Intelligence Service—remained in Geneva to perform the heavy task of preserving what could be preserved of the work of the past and of adapting the efforts of the Health Organisation to the new conditions resulting from the hostilities. In the early years of the war national health services were helped both by direct action and by the supply of documentation and technical advice and reports were prepared for their guidance on such subjects as the medico-social problems arising from the displacement of civil populations. Data were also supplied on a variety of matters including the food ration consumed before and during the war in the occupied countries the foodstuffs most suitable for distribution in concentrated form to the populations of these countries after their liberation and the types of vitamin deficiency disease that were most to be feared.

Later in 1943 the Officer in charge of the Health Service of the League was sent first to London to place at the disposal of the Inter Allied Services the experience acquired by the Health Organisation in connexion with the combating of epidemics the prophylaxis of contagious diseases and assistance for pregnant women and newborn infants and then to Washington to give to the Office of Foreign Relief and Rehabilitation the benefit of the League's nutritional malarial and sanitary engineering experience and to develop collaboration between the League Health Organisation and the Health Division of UNRRA which was in process of organization. Arising from this the League's Health Section established a research unit in Washington in 1944—staffed by its former Chief of the Epidemiological Intelligence Service at Geneva and by the former statistician of the League's Singapore Bureau—which has since become the Epidemiological Intelligence Service of the Health Division of UNRRA.

Meanwhile many of the pre-war long term activities of the League Health Organisation continued including the work on biological standardization on the unification of the national pharmacopoeias and on malaria rables and nutrition.

After this account of the work of the Health Organisation the remainder of Chapter 2 is devoted to the League's work on the control of the drug traffic international assistance to refugees the settlement of the Assyrians of Irak and technical collaboration with China.

The remaining chapters deal with Mandates Intellectual Co-operation Questions of a Legal and Administrative Character and the Library at Geneva. The report ends with a list of the League of Nations Publications from January 1st 1940 to October 31st 1945.

This account of the first great experience in international co-operation for peace and human progress goes far to show that the League did not fail it was the nations which failed to use it. If the lesson is learned that however effective the machine may be the outcome will depend on how it is used on the justice wisdom and courage of leaders and above all on the vision and determination of the common people it will have contributed much to the success of the new venture on which the United Nations are now embarking.

LEWIS'S MEDICAL, SCIENTIFIC & TECHNICAL LIBRARY Catalogue of Lewis's Medical, Scientific and Technical Lending Library Part I.—Authors and Titles. Part II.—Classified Index of Subjects, with Names of Authors who have written upon them. New Edition. Revised to the end of 1943. pp. 8+928. 1944. London H. K. Lewis & Co. Ltd. 136 Gower Street W.C.1 [To subscribers 12s. 6d. to non-subscribers 25s. (Review appears also in *Bulletin of Hygiene*)]

Lewis's Medical, Scientific and Technical Library is exceptional, if not unique in that it issues regularly in volume form complete and reasonably up-to-date catalogues of the books available in the library. The present edition of Lewis's Library Catalogue has been revised to the end of 1943 and Part I which runs to 714 pages includes some 24,000 titles of books of importance—British, American and English translations of Foreign works—in medicine and science generally arranged alphabetically under Authors names. Part II of the Catalogue provides an alphabetical index of the Subjects covered by the Library with the names of authors who have written upon them. Thus by reference from the authors names given under the subject headings in Part II to the entries under authors names in Part I of the Catalogue readers are enabled to find the full titles dates of publication, numbers of the latest editions, prices and, in the case of foreign books, the places of publication of works on any particular subject of medical or scientific interest. Librarians as well as readers will thus find the Catalogue a most useful source of reference to books published on medical, scientific and technical subjects.

TROPICAL DISEASES
BULLETIN

Vol. 43.]

1946

[No 4]

SUMMARY OF RECENT ABSTRACTS *

III MALARIA

[Continued from p 184]

Treatment

General.—In a comprehensive discussion of the principles governing the curative and suppressive treatments of malaria, especially in relation to military conditions SIMON (p 694) defines subdivisions of the terms prophylaxis suppression and cure and relates the procedures defined under these headings to the state of immunity of the troops (white and non-white) and to the malaria conditions to which they may be exposed. It is not possible further to condense this abstract the author has taken into account all information available on the subject.

FINDLAY *et al* (pp 6 350) in a study of the treatment of malaria in British troops in West Africa, all the infections being due to *P. falciparum* conclude that mepacrine is as satisfactory as quinine or as quinine followed by mepacrine provided that 0.8 gm. is given in the first 24 hours of treatment. No toxic symptoms were seen although some of the patients had been taking suppressive doses of mepacrine for several months beforehand. Quinine however should be used in cerebral malaria, hyperparasitism in the rare cases in which the high temperature fails to react to mepacrine and in the still more rare cases in which mepacrine causes vomiting or psychotic change.

In the *Army Medical Department Bulletin* (p 692) it is stated that a quinine-pamaquin course was more successful than a mepacrine course in the treatment of relapses of *P. vivax* malaria. Subsequent relapses were significantly fewer after the quinine-pamaquin than after the mepacrine course during a follow up period of 5 months. Details are given.

Evidence is brought by CHEN and GEILING (p 348) to show that after intravenous injection quinine and mepacrine are rapidly removed from the circulation by an adsorption process which takes place in the capillaries especially those of the lung. Quinine is rapidly destroyed by enzyme action but the metabolism of mepacrine in the tissues is slow and the process is not yet understood.

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945, v 42. References to the abstracts are given under the names of the authors quoted and the page on which the abstracts are printed.

In March 1944 TENKIN and RAMSEY (p. 533) issued a monograph on anti-malarial drugs. This is a review of information published in the literature and was compiled as a basis for the revision which the military situation demanded but it does not include the newly-acquired information then restricted to confidential reports, and may therefore be misleading to the student unless this is borne in mind.

QUININE etc.—The effect of acid and alkali on the absorption and metabolism of quinine has been studied in animals by ANDREWS and CORWATZER (p. 534) who found that there was no evidence that alkali therapy significantly delayed excretion. The lowered percentage excretion of quinine during alkali administration which has been noted by others was confirmed, but the results are not explained by differences in absorption following administration of acid or alkali. The same authors have studied the rate and degree of absorption from the intestinal tract: the dihydrochloride is more quickly absorbed than the sulphate but differences in the rates decrease with time.

PINK and ENGELBERG (p. 964) show that administration of quinine has the effect of reducing the prothrombin level of the blood. Soldiers receiving it would therefore be in danger of prolonged bleeding should they be wounded and the authors advocate the concurrent administration of vitamin K in such circumstances.

HEILIG and VESVESNAR (p. 442) show that quinine when given intravenously on several successive days has a definitely deleterious action on the myocardium, and leads to lowering of the blood pressure probably through an action on the peripheral vessels. They conclude that quinine should not be given intravenously unless there is a specific indication. DREISBACH and HANZLIK (p. 964) agree that quinine given intravenously has a depressant action on the circulation which in cases of severe quinine collapse may be irreversible: they have found that epinephrine, neosynephrine and calcium chloride, when mixed with the quinine, have an action in mitigating this depressant action. Details of dosage are given.

KHAN (p. 861) as a result of a considerable experience in a military hospital, states that a not inconsiderable proportion of blood slides of patients seriously ill from malaria were repeatedly negative for parasites, and that in some fatal cases where this was so sporulating forms were found in the capillaries of the brain post mortem. In the majority of serious cases however the blood was heavily infected. In suspected cases of cerebral malaria, intravenous quinine should be given immediately but for further treatment the author favours intramuscular methyl-sulphonate mepacrine. For cerebral malaria FITZ HUGH *et al.* (p. 340) gave intravenous injections of quinine, well diluted in saline or saline-glucose and administered slowly. As much as 3 or 4 gm. quinine may be given in 24 hours. Intravenous sodium amytal is most useful in convulsions or mania, and spinal drainage in coma. Blood or plasma transfusions are valuable for anaemia or symptoms of shock.

METCALF and UNGAP (p. 341) describe patients with *P. vivax* malaria contracted in the Solomons who had to be repatriated to the United States because of relapses. These men were unable to achieve immunity strong enough to permit them to remain abroad and treatment with mepacrine was not efficacious. The drug of choice was quinine in heavy dosage: there was little advantage in using mepacrine, pamaquin or neosyrphenamine with the quinine. In these men a low degree of parasitaemia was capable of producing a severe rigor.

For the treatment of relapses of *P. vivax* malaria, in men returned to Britain from abroad MASON BARR (p. 176) advocates the use of Solvochin, a preparation of quinine for intramuscular injection the dose of which contains 0.5 gm. quinine. The injections (two daily for two days) should be followed

by a course of quinine by the mouth and of pamaquin. For *P. falciparum* infections more injections may be needed followed by oral quinine and mepacrine. Solvochin contains antipyrin. HAWKING (p 536) has shown that the lesions it causes in muscle are indistinguishable from those caused by quinine. BROWN (p 779) has found X ray evidence of calcified cysts in the gluteal region of European and Indian soldiers who have received intramuscular injections of quinine. Their appearance is characteristic, but they give no trouble.

RAYMOND (p 250) shows that the totaquina (type I) prepared in Tanganyika Territory contains all the cinchona alkaloids and though in somewhat larger dosage is practically as useful in treatment as quinine. He argues that totaquina of this type is the most economical and effective means of using the anti-malarial action of cinchona bark. A comment in the *East African Medical Journal* strongly supports this view (which indeed is widely held) and urges standardization of totaquina. A controlled experiment carried out by GREEN (p 442) shows that treatment of malaria (chiefly *P. vivax* infections) with totaquina was about as effective as treatment with quinine but that mepacrine was more successful in preventing early relapses than either totaquina or quinine.

RICO (p 177) reports favourably on a gluconate of quinine and calcium in treatment.

The distribution of quinine and other cinchona alkaloids in the fluids and tissues of dogs has been studied by HIATT and QUINN (p 778) for details the original abstract should be consulted. UNTI (pp 90 697) describes a simple method for the estimation of quinine in blood. HIATT (p 178) has determined the plasma concentration of alkaloids of cinchona at various times after a single oral administration.

MREAD and KORPFLI (p 9) discuss the structure of a quinine derivative obtained by allowing rabbit liver to react with quinine *in vitro*.

DAVIDSON (p 964) has found that burasaine (a mixture of alkaloids) has some definite antimalarial properties.

Mepacrine—In 1944 the Medical Research Council Committee on Malaria (p 88) issued a statement on mepacrine in which they reproduced a resolution made by the United States Board for the Co-ordination of Malarial Studies. There was very close agreement between the opinions expressed which may be summed up as follows. Under proper administration mepacrine is no more liable than quinine to cause toxic effects. mepacrine is as effective as quinine in the treatment of *vivax* malaria but neither compound will prevent relapses. If properly given mepacrine will practically always suppress and cure *falciparum* malaria, but the action of quinine in this respect is less certain. The Americans point out that mepacrine is effective in suppression [they do not distinguish species in this respect] and that doses of quinine sufficient to produce the same result frequently cause symptoms of cinchonism.

In an important paper on the pharmacological basis of mepacrine therapy in malaria SHANNON *et al.* (p 343) show that the concentration of this drug in leucocytes is more than 200 times as great as the concentration in plasma, and that the ratio between the concentrations in whole blood and plasma varies considerably for a number of reasons. When blood is shed, the mepacrine tends to be released from the leucocytes and it is therefore important that the blood should be centrifuged immediately after withdrawal if the plasma estimations are not to be vitiated. Most of the mepacrine in plasma is bound to the proteins. In the different organs of the body the concentration of mepacrine varies greatly being highest in the liver and only relatively small fractions are retained in the plasma. Excretion of mepacrine is slow and accounts for only 1-5 per cent. of the daily dose. degradation is also

slow and mepacrine can therefore accumulate in the body to reach a point of equilibrium which varies in different individuals. Protection against malaria, as noted by HAWKING in comment, is probably achieved at a plasma concentration of about 20 microgm. per litre and this is attained most quickly by high initial dosage. Similarly for treatment a high initial dosage should be used for this mepacrine may be injected intramuscularly but the intravenous route is not advised. Subsequently it should be given by mouth. Details will be found in the original abstract.

MASEN (p. 8) describes a method for the fluorimetric estimation of mepacrine in blood and urine which is sensitive to 0.1 mgm. per litre. Details should be sought in the original. AUERBACH and ECKERT (p. 90) have used a modification of this method which is described.

MARGRAITH *et al.* (p. 251) have shown that the concentration of urinary mepacrine is proportional to that of plasma mepacrine and to that of urinary ammonia so that if any two of these values are known the third can be calculated by means of a simple formula. Plasma concentration, which is a most important factor is difficult to determine but urinary mepacrine and ammonia concentrations can be estimated simply by means of a Lovibond disk. KING and GILCHRIST (p. 781) describe a method for estimating mepacrine in urine for details of which the original abstract should be consulted, and BROWN and RENNIE (p. 780) and MARGRAITH *et al.* (p. 780) have observed that in persons who have been taking suppressive mepacrine for some weeks the plasma mepacrine can be calculated from a formula which takes into account urinary mepacrine, urinary NH_3 , and a constant. The latter workers (p. 779) show that the error in this procedure is very small, and that the apparatus is simple. The method can be adapted to régimes of mepacrine administration other than suppressive doses but for each régime special measurements are necessary.

YUDKIN (p. 863) describes three simple methods for the estimation of mepacrine in urine for details of which the original abstract should be consulted.

KING and GILCHRIST (p. 782) describe a field method for the estimation of mepacrine in plasma and blood details cannot be given in brief space. The method depends on fluorescence as does that described by HENRY and GIMBLEY (p. 783) for estimation of stilbamidine and mepacrine in urine.

A paper was published in the *Lancet* (p. 342) by the Army Malaria Research Unit, which showed that in estimation of plasma mepacrine the anticoagulant used should not contain ammonia, since ammonia displaces mepacrine from the leucocytes (which have a high concentration of the drug) and therefore leads to grossly exaggerated plasma readings. Potassium oxalate, sodium citrate and heparin are satisfactory anticoagulants.

LEWIS (p. 434) describes a method details of which are given in the original abstract for estimating concentrations of mepacrine in serum. In comment, HAWKING points out that since vastly larger amounts of mepacrine are held in leucocytes than in plasma the separation of serum introduces the probability of error by liberation of mepacrine from the white cells. The ideal is to estimate mepacrine in plasma separated from cells within 15 minutes of withdrawal from the body if this cannot be done mepacrine should be estimated in whole blood, a leucocyte count being made so as to guard against gross abnormalities.

ALLEN (253) points out that patients who have taken large doses of mepacrine may develop a mental condition similar to that of general paralysis, and that a false positive Wassermann reaction may be found, in such cases as a result of malaria. The results that may follow such a mistaken diagnosis are obvious. GASKILL and FRIZ HUGH (p. 629) report toxic psychosis in 0.4 per cent. of soldiers suffering from malaria and treated with mepacrine most

of these patients recovered. GELLER (p. 9) has not found that relatively large doses of mepacrine produce nervous symptoms. In comment HAWKING states that psychotic symptoms due to mepacrine have occurred but rarely in the wide experience gained in the recent war and that such symptoms usually disappear when the mepacrine is discontinued.

In *Nutrition Reviews* (p. 8) a summary is made of the evidence which shows that mepacrine in high dosage may have a toxic action in animals poorly nourished especially in regard to proteins.

SIEGEL and MUSHETT (p. 178) give an account of the pathological changes induced in animals by administration of large doses of mepacrine. For details the original abstract should be consulted. SIEGEL *et al.* (p. 628) show that very large doses of mepacrine given to rats on a low protein diet caused damage to the liver but in comment HAWKING points out that in man the ordinary suppressive dose does not produce any visceral lesions. In men treated for malaria with courses of mepacrine in fairly high dosage BUTT *et al.* (p. 783) could find no evidence of damage to the liver a conclusion which agrees with that of military investigators in the British Army.

In experiments with young rats HEGSTED *et al.* (p. 784) have found that mepacrine has a thiamin sparing action.

THOMPSON (p. 695) has treated relapses of *P. vivax* malaria with large initial doses of mepacrine with some apparent benefit over courses comprising smaller doses. SMITH and PASSALACQUA (p. 696) also write favourably of the effects of large doses of mepacrine especially in *P. vivax* malaria.

The pharmacological action, especially as regards toxicity of eight salts of mepacrine was studied in animals by BARLOW *et al.* (p. 443). Details should be sought in the original.

BOSE *et al.* (p. 444) show that a butyl acridine derivative (the corresponding amyl acridine compound being mepacrine) has considerable effect in *P. vivax* and *P. falciparum* infections.

Pamaquin etc.—WEST and HENDERSON (p. 253) give a list of symptoms which they attribute to the use of pamaquin (plasmoquine) in doses of 0.01 gm daily for 5 days in American troops overseas. These symptoms include jaundice abdominal pain anaemia headache weakness and dizziness. In comment HAWKING observes that it is difficult to exclude other factors as causes of this syndrome and points out that no such complaints were made in a considerable group of British soldiers treated in much the same way.

SHISHLAIEVA MATOVA (p. 351) produces evidence that the compound Quinolone No. 31 [the chemical name of which is given in the abstract] is about as effective as pamaquin in preventing infection of mosquitoes with both benign and malignant tertian parasites.

Other Drugs—COGGESHALL *et al.* (p. 698) have shown that sulphadiazine has no value in preventing relapses in *P. vivax* malaria naturally acquired in the South-West Pacific.

HARNED and ETTELDORF (p. 443) show that sulphathiazole can be administered concurrently with quinine or mepacrine. In malarious districts such a combination is necessary when bacterial diseases and malaria co-exist.

KAY (p. 696) found no advantage from giving three injections of Mapharsen in conjunction with mepacrine in the treatment of relapsing *P. vivax* infections. On the other hand DAO (p. 697) reports good results from the use of this drug alone in *P. vivax* infections infections being given at intervals of 4 to 7 days for courses of eight injections.

HINDLE *et al.* (p. 446) have found that penicillin is without effect in malaria.

Suppression.

FINDLAY and STEVENSON (p. 349) recount the history of drug suppression of malaria in West Africa during the war. Quinine in 5-10 grain doses was not satisfactory; mepacrine (0.4 gm. each week) was better but the best results were obtained with mepacrine 0.1 gm. daily except on Sundays. Figures are given which demonstrate these facts beyond doubt. The only cases of cerebral malaria were in men who either had not taken mepacrine or had taken it irregularly. The use of mepacrine appeared to reduce the number of cases of blackwater fever. [The findings in West Africa are therefore in line with those of workers in New Guinea.]

FAIRLEY (p. 656) comments on the high rate of malaria experienced by the troops in New Guinea before the use of suppressive mepacrine became universal. To test the suppressive and therapeutic effectiveness of mepacrine, quinine and certain sulphonamides FAIRLEY (p. 630) and his associates made very careful investigations on healthy volunteers in Australia. These men were infected with Papuan strains of *P. falciparum* or *P. vivax* and were subjected to most rigorous conditions. The author makes the point that no instance was seen of failure to infect the normal white man unless he was protected by a drug. The sulphonamides suppress *P. falciparum* but not *P. vivax*; mepacrine in a daily dose of 0.1 gm. suppresses and will cure *P. falciparum* infection if continued for some weeks after exposure but though it suppresses it it will not usually cure *P. vivax* infection. Quinine is not nearly so effective. Institution of suppressive mepacrine as a routine and made a disciplinary measure in the troops in New Guinea brought about a most dramatic reduction in the incidence of malaria but the problem of relapses of *P. vivax* after cessation of mepacrine administration remains. In this work it is shown that though blood is infective for a few minutes after infection by bite it becomes uninfected until the 7th (*P. falciparum*) or 9th (*P. vivax*) day: sporozoites are apparently rapidly removed by macrophages and fixed tissue cells.

In the *Royal Naval Medical Bulletin* (p. 179) recommendations made in the United States Navy for the use of mepacrine as a suppressive are reproduced. These follow the accepted dosage of 0.1 gm. daily and the point is made that the treatment should be commenced a month or more before arrival in the malarious area or that if time is short 0.2 gm. daily for a week should be taken to build up the necessary blood concentration.

McCoy (p. 785) sums up the use of mepacrine for suppression of malaria, in doses of 0.1 gm. daily. Symptoms of intolerance usually pass off quickly. They very rarely persist. It is necessary to attain the required plasma concentration by administration for some time before exposure to malaria, and it may be necessary in military operations to continue administration for some time after cessation of exposure. There is no evidence of the production of mepacrine-resistant strains of parasites as a result of long-continued administration.

From investigations in Lebanon MEASHAM *et al.* (p. 695) conclude that mepacrine though not a true prophylactic is a useful suppressant, and that if continued long enough it cures infections at a subclinical level.

Suppressive treatment with mepacrine and pamaquin given on two successive days every 5 days was found by LEITMAN (p. 254) to be useful in the prevention of malaria in Tashkent. In a comparison of the effects of mepacrine alone and of mepacrine together with pamaquin in adult doses of 0.3 gm. and 0.03 gm. of the two substances weekly scaled down for younger persons PARROT *et al.* (p. 445) found that neither was effective in preventing malaria in the inhabitants of a hyperendemic area of Algeria.

MACGRAITH and HAYARD (p. 863) made long and detailed studies on some 500 volunteers in relation to the effects of mepacrine taken in suppressive doses. They concluded that the drug is both safe and effective. As a result of careful examination of 102 soldiers DREW and REID (p. 862) think that prolonged administration of mepacrine in suppressive doses does not lead to any cumulative toxic action and that there is good reason to believe that its protective action is very great. McCORKLE (p. 536) concludes from an investigation that prolonged administration of mepacrine in suppressive doses has no deleterious action on the liver and in comment HAWKING states that elaborate investigations in Britain have led to the same opinion.

RUSSELL (p. 630) produces evidence which suggests that mepacrine in suppressive doses tends to produce some degree of eosinophilia.

ROMERO MOLINER (p. 180) shows that in Fernando Po a daily dose of 0.4 gm. quinine was not an effective suppressive. Atepe (containing mepacrine and pamaquin) was much more successful.

Control.

In an address on the need for a malaria control policy for rural Africa MACDONALD (p. 965) claims that in spite of the relative immunity attained by Africans after the age of childhood malaria still continues to be a cause of ill health in adult life and he is not content with the view that it is unwise to attempt malaria control because anything less than complete control would interfere with immunity. He advocates experiments on a large scale in which all the methods now available should be used together with improvement of the whole circumstances of African life. ANNICKS *et al.* (p. 966) on the other hand restate the argument that incomplete control would make matters worse in the hyperendemic areas. They see more hope from improvement of environmental conditions and nutrition so that the Africans may be more able to resist malaria than from control by methods now used. They too advocate continued research and experiment on a large scale but think that the means of control now available are not likely to give satisfactory results in the areas concerned and under existing conditions. A single and cheap form of attack is required.

SYMES and HADAWAY (p. 785) have made a detailed investigation of the effect of DDT in solution or as an emulsion in killing adult mosquitoes in dwellings in British Guiana. The results were very good and the residual action most notable—in one area the reduction of anophelines (compared with control houses) was 89.9 per cent. 7 weeks after application. *Anopheles darlingi* is more susceptible than *Culex fatigans* to DDT. Discharge into the open air is also effective but needs investigation. The authors note that in the daytime *A. darlingi* frequents ground shaded by vegetation and that ground-spraying is therefore essential.

RICE *et al.* (p. 632) show that Thanite, a terpene thioacyano ester incorporated in DDT sprays greatly increases the immediate knock-down effect—the residual lethal action however is due to DDT.

EDDEY (p. 255) describes the programme of spray-killing of adult mosquitoes (chiefly *A. gambiae*) which was undertaken in Takoradi during the war. The best results were obtained with pyrethrum aerosol and pyrethrum in kerosene (DDT evidently not being available). The procedure was popular and malaria rates are quoted which suggest that there was a substantial reduction of incidence as a result of this measure.

Dusting of African huts with pyrethrum powder at the rate of 2 ounces per 1 000 cubic feet twice each week was found by GARNHAM and HARPER (p. 447) to reduce by about 50 per cent. the amount of malaria in a village in Kenya at an altitude of 5 000 ft., in which transmission was largely seasonal.

SENIOR WHITE and VENKAT RAO (p. 180) have made an extensive study of the daily movements of *Anopheles* of the *flavirostris* group (*flavirostris minimus* and *parvus*) in relation to houses baited with man or animals, and of the effects of spraying (at various intervals) on the older (and potentially infective) mosquitoes. The rationale of spraying is to destroy the mosquito before it becomes infective, i.e. before the 9th-14th day according to the time of the year. The authors therefore suggest that spraying should be spaced so that any mosquito will twice run the risk of being hit before its glands become infected. By daily spraying the density of mosquitoes was (in one experiment) reduced 24 fold by intermittent spraying, with intervals of not more than 2 days 6-fold. The oocyst and sporozoite rates of the mosquitoes caught did not vary much but it is by the reduction of density that malaria control is achieved. *A. culicifacies* however can be controlled by weekly or at most twice weekly spraying. For details the original abstract should be consulted.

GILROY and CHWATT (p. 786) describe their method of draining that part of the foreshore near Lagos, which is covered by the sea only by high tides, and in which there are many crab holes and shallow pools. This zone is the chief breeding place of *A. vexans*. By constructing an embankment on the seaward side of this zone and draining the zone by one-way gates through the embankment the authors effected a marked fall in anophelines over a large area; the malaria rate also fell, but there may have been additional reasons for this notably the removal of the local population of gametocyte carriers.

COLLIGNON (p. 686) reports on anti-malarial measures taken in the Department of Algiers during 1943.

Emulsions of mineral oils have successfully been used in larval control by KANCHAVELI (p. 632).

WASICKY and UYTI (p. 182) have tested DDT in a colloidal preparation, as a larvicide. A dilution of 1 in 50 million kills mosquito larvae in 24-36 hours and there is a residual action in gradually diminishing potency for several weeks.

ROZENOOM and HESS (p. 182) show that there is a close positive correlation between the production of *A. quadrimaculatus* and the extent of intersection line between plants, water and air. High intersection line values conduce to increased oviposition and decreased larval mortality. HESS and HIXER (p. 183) describe the means by which the breeding of *A. quadrimaculatus* is controlled on the great reservoirs of the Tennessee Valley Authority. By bringing the water level to full during winter or spring, and then reducing to summer level, much of the floatage is stranded and rendered harmless. Later a constant level reduces the amount of subsequent marginal vegetation but from the beginning of moderate *quadrimaculatus* production weekly fluctuation of level eliminates the intersection line and produces a clean shoreline. The permanent works undertaken for the control of *Anopheles* breeding on the Kentucky reservoir of the Tennessee Valley scheme are described by BISHOP and GARTRELL (p. 184) who show that in projects of this kind such works are more economical than the larvicidal and shore line maintenance programmes which would have been necessary had they not been done. Details must be sought in the original.

A description of technical methods in the use of aeroplanes for dusting with Paris green is given by KRUSE *et al.* (p. 184). This method of mosquito control is largely used in the Tennessee valley. METCALF and HESS (p. 354) note that when Paris green is used from aircraft, only about 25 per cent. reaches the treatment area, the rest being dispersed by wind and propeller action. They found that if particles of larger size (20-50 microns) than usual are employed there is a 60 per cent. increase in the amount which reaches the treatment area, and that particles of these sizes are, in fact ingested by larvae of *A. quadrimaculatus*. They therefore recommend the use of larger particles.

SCHOOF (p. 537) shows that non-baited anopheline houses—rough wooden structures easily made and transported—afford the most useful means of observing adult *A. quadrimaculatus* in relation to control measures.

MULRENNAN *et al* (p. 633) quote instances of potential malaria vectors from foreign countries being found in the United States and comment on the need for strict supervision of aircraft which may bring such dangerous species.

Malaria of Birds and Monkeys

BROOKE (p. 864) gave to canaries diets in which there were certain deficiencies comparable with deficiencies in human diets in parts of the United States and elsewhere. He observed the effect of these diets on the course of infection with certain bird malaria parasites in general this was to cause the birds to suffer from more severe primary attacks and to reveal a greater tendency to relapse and a reduced resistance to superinfection. Biotin deficiency increases the severity of certain avian malarial infections but SEELER and OTT (p. 540) produce evidence that riboflavin deficiency has rather the opposite effect.

SEELER (p. 699) has found that administration of pyridoxime definitely inhibits the action of quinine and mepacrine in certain malaria infections of ducklings but does not influence their toxicity. It is not known how pyridoxime acts in this respect.

WRIGHT and SABINE (p. 252) discuss the effect of mepacrine on the oxygen consumption of tissues and HAAS (p. 252) has investigated the effect of mepacrine and quinine on isolated respiratory enzymes. Readers are referred to the original abstracts for the results of these highly technical studies.

SPECK and EVANS (p. 967) have shown that *P. gallinaceum* like *P. knowlesi* forms lactic acid from glucose. They discuss the action of quinine and mepacrine on the metabolic activities of *P. gallinaceum* in relation to therapeutic activity. SILVERMAN *et al* (p. 448) have studied the metabolism of *P. gallinaceum* *in vitro* but for details of this intricate work the reader should consult the original abstract.

A comprehensive description is given by HUFF and COULSTON (p. 538) of the development in chickens of *P. gallinaceum* from sporozoite to erythrocytic trophozoite. The sporozoite whether injected by syringe or mosquito bite develops in macrophages divides into cryptozoic merozoites which in turn give rise to metacryptozoic merozoites which enter either other macrophages or erythrocytes. A later stage of development consists of the formation of larger numbers of small (micro-) merozoites and at this stage there is a sudden flooding of the blood with erythrocytic forms. The only species of malaria parasites in which cryptozoites have been found are those in which abundant exo-erythrocytic stages occur. It should not be assumed that all species of *Plasmodium* must develop in the same way. This description of the development of *P. gallinaceum* is the first complete account which has been given.

CANTRELL and JORDAN (p. 633) have found all species of *Aedes* tested to be susceptible to *P. gallinaceum* infection. *Culex pipiens* is resistant.

HAAS and EWING (p. 539) have succeeded in infecting chick embryos with *P. gallinaceum* by inducing infected mosquitoes to feed through the shell membrane. HAAS *et al* (p. 865) have devised a technique for making serial passages of *P. gallinaceum* in chick embryos. They note that a green discoloration of the membranes amniotic fluid yolk liver and spleen is diagnostic of malarial infection.

COATNEY *et al* (p. 865) discuss the results of experiments on infection of chicks with *P. gallinaceum* either by the bite of a single infected *Aedes aegypti* or by injections of sporozoites or of comminuted whole mosquitoes. The last is the method of choice for inducing infection for studies in chemotherapy.

non-malarious areas 10.8 for larger spleens the rates were 11.1 and 3.2, a significant difference. It would seem that PDI spleens [palpable on deep inspiration only] should be disregarded in surveys of places of low malaria endemicity. Palpable spleens were slightly more frequent in children with a history of recent illness, measles, chickenpox, etc., than in other children.

It is interesting to note that, ignoring spleens palpable only on deep inspiration, enlarged spleens were more frequent in New York children 3.7 per cent. than in Massachusetts children, 1.0 per cent. Both localities are free from endemic malaria.

Nearly all the children examined were between 5 and 12 years of age.

Norman White

SPICER S. S. The Spleen Survey as applied to the Measure of Malaria in the United States—a Review of the Literature. *J. National Malaria Soc.* Tallahassee, Fla. 1945 Sept., v 4, No. 3 165-82. [Numerous refs.]

During the war a thick blood film survey was carried out throughout the endemic malaria areas of the United States. 100 000 thick films were examined. Less than 0.2 per cent. of these were positive, and nowhere was the rate high enough for checking the results of malaria control measures. At the same time in Florida 20 to 25 per cent. of school children were found to have palpable spleens though less than 1 per cent. had positive blood slides. Partly to explain this situation, the author has made a study of the literature to determine the value of splenometry in the conditions of low endemicity prevailing in the United States. Among the results of the inquiry are the following conclusions:—

A recent epidemic of one of the childhood diseases, and possibly a high rate of infections of the upper respiratory tract, may increase the spleen index. A proportion of apparently healthy children have spleens that are palpable on deep inspiration. Spleen rates as high as 15 per cent. may occur in the absence of malaria—these will be almost all PDI spleens [palpable on deep inspiration only]. Spleen rates above 15 per cent. are probably significant of malaria. A fall in the malaria rates over several years causes a quicker decline in parasite rates than in spleen rates. The spleen index in a community may remain high for several years after a malaria epidemic, partly as a result of relapses, and thus reflects the rate of transmission during the preceding several years. Quinine medication causes a reduction in spleen mass. Spleen rates are influenced by race, age and parasite species. Greater enlargement occurs in the white than in the coloured race, and in children than in adults.

SAUTETAS L. Paludisme autochtone. L'épidémie de Camargue. [Indigenous Malaria—the Camargue Epidemic.] *Rev. Paludisme et Méd. Trop.* 1945 Apr. 15-May 15 v 3 No. 15-16, 81-3

This is a brief account of an epidemic of malaria in Camargue in 1943 and is based on a report published by J. SAUTET in the journal *Marseille Médical*. Camargue is the region enclosed by the two main branches of the river at the mouth of the Rhône—the only French delta. The inhabitants have always led a somewhat precarious existence in this low-lying tract, with its numerous marshes of varying degrees of salinity. Mosquitoes are abundant and malaria was endemic, but the disease had been very little in evidence during the previous decade—local inhabitants said that it had almost disappeared. The outbreak reported occurred in September 1943. There were 177 cases recorded among the inhabitants of les Saintes-Maries-de-la-Mer and adjacent farms; hospital patients at Arles. Annuité labourers employed in the recently created

rice-fields Russo-Polish workers and young workers who had come to help gather the grape harvest Sautet considered that this number represented not more than half the real incidence. All were *P. vivax* infections of an extremely mild type which showed no tendency to relapse Blood examination showed gametocyte carriers to be exceedingly rare this, according to Sautet is characteristic of places in which malaria is in process of disappearing The vector was *A. maculipennis* var. *cambarumaci* it was abundant but not noticeably more so than in previous years The local population blamed the ricefields but the vector species was not found breeding there The indigenous population of Camargue has evidently a high degree of resistance to the local strain of *P. vivax* The author suggests that susceptible arrivals should take prophylactic quinine during the transmission season.

GUHL R. Zwei Falle von autochthoner Malariainfektion in der Schweiz [Two Cases of Autochthonous Malaria in Switzerland.] *Schweiz. med. Woch.* 1946 Jan 26 v 76 No 4 67-9 1 fig. [14 refs]

POLUNORDVINOV A D [Highland Malaria in Southern Tadzhikistan.] *Med. Parazit. & Parasitic Dis.* Moscow 1945 v 14 No 2 18-20 [In Russian]

The author reports the occurrence of endemic malaria due to *Plasmodium vivax* *P. falciparum* and *P. malariae* at altitudes up to 2750 and 2850 metres [ca. 8,920-9,248 feet] above sea level in the mountains of Southern Tadzhikistan (Middle Asia) These altitudes represent practically the limit of human settlement in the region in question.

GARCIA SASTRE L. Notas sobre el paludismo en la isla de Gran Canaria. [Notes on Malaria in the Island of Gran Canaria.] *Rev. Sanidad e Hig. Publica* 1945 Apr v 19 No 4 257-71 7 figs. (2 on 1 pl.)

It is almost certain that malaria has existed in the Island of Gran Canaria since very ancient times Recorded information as to its extent and distribution is scanty Climatic conditions are eminently favourable for anophelines and travellers records of 1775 and 1803 refer to the great prevalence of tertian fevers in the island. Parts of it however remain free from malaria. In the capital Las Palmas no anophelines were found among 18,826 mosquitoes examined the few cases of malaria that occurred there in 1944 were all due to infections contracted elsewhere. In the south and centre of the island malaria has long been endemic Medical reports refer to the large spleens and earthy complexions of some of the inhabitants notably the children, but without other noteworthy clinical manifestations of malaria.

During the last three months of 1941 an outbreak of malaria occurred in a labour force engaged on construction work between Fataga and Maspalomas There were 77 cases The source of infection may have been a man who contracted malaria in the neighbourhood of Seville. No further cases were reported during the first eight-months of 1942, but the closing four months of that year witnessed a second outbreak of 113 cases in localities adjacent to the infected area of the previous year In June 1943 malaria reappeared in the north-east and south west of the island and the ensuing epidemic involved 8 of the 21 administrative divisions. In all 2164 cases were recorded in 1943 the highest incidence being in the middle of the southern half of the island. During 1944 cases were reported in every month of the year in fact there was only one week in February in which no new case was notified. The total cases for the year numbered 3,978 and 13 of the 21 *municipios* were involved. Once again the *municipios* of San Bartolomé and Santa Lucia, in the south and centre suffered

most here the incidence was equivalent to 190 and 180 per 1,000 of the population. The north-east of the island escaped. The maximum incidence in 1944 was in September 971 cases, and the lowest in February and March, 28 cases each. Some of the greatly increased incidence in 1944 as compared with the previous year may have been due to the fact that the local medical profession had become more malaria-minded as the result of circulars, propaganda and the like. Of 3,406 cases in 1944 *P. vivax* was responsible for 1,722, *P. falciparum* for 1,680 and mixed infections for 24. *P. malariae* was not observed.

Work with regard to the malaria vectors has not been completed. It would seem that the vectors belong to the *Anzomyia* group probably *A. hispaniola* and *A. sergenti*. Although no anopheline breeding could be found in the urban area of Las Palmas, important breeding places were found in four localities at distances of no more than from 6 to 12 kilometres away.

In view of the rapid spread of infection to places that have been hitherto immune it is not unlikely that the whole island will soon be involved.

NÁJERA, L. La fauna anofelica de las islas Canarias. [The Anopheline Fauna of the Canary Islands.] Reprinted from *Boletín de la Real Soc. Española Hist. Nat. Madrid*, 1944, v. 42, 325-6.

The author notes that no anophelines were mentioned by BECKER (*Dipteren der Kanarischen Inseln und der Insel Madeira*, Berlin, 1908) and that the only species found later have been *A. hispaniola* (by Graham) and *A. sergenti* (by Christophers). He writes of a collection of mosquitoes recently acquired from a collector in the islands and now deposited in Madrid. Charles Wilcocks.

LE GALL, R. Le paludisme en Afrique Occidentale Française au Togo et à Madagascar en 1941. [Malaria in French West Africa, Togo and Madagascar in 1941.] *Bull. Office Internat. d'Hyg. Publique*, 1944, May-June, v. 36, Nos. 5-6, 203-24.

This report brings together information concerning the prevalence of malaria during 1941 in each of the Colonies of French West Africa, the mandated territory of Togo and in Madagascar. As elsewhere in the world, complete statistical information regarding mortality caused by malaria is non-existent. The ratio of malaria cases treated to the total number of sick persons seen in hospitals, dispensaries, infant welfare centres, travelling dispensaries, etc., varies somewhat from year to year and provides some indication of the fluctuations in malaria incidence. Such information suggests that malaria was somewhat more prevalent in 1941 than in either of the two previous years, but the differences were not great. In Madagascar exceptional rainfall was responsible for very severe malaria: one third of all sick persons treated were suffering from that disease.

Of special interest in the report is the reference to an inquiry that was carried out in the Comores archipelago, which lies to the west of the northern tip of Madagascar. Malaria was found to be endemic in all the islands, but in varying degrees of severity. Mayotte and Mohéli are the islands most severely affected. In Mayotte spleen rates varied between 40 and 80, and parasite rates from 10 to 18. In Mohéli, there were spleen rates of 50 to 80 and parasite rates of 20 to 35. *P. falciparum* infections were predominant. Anjouan is the island least affected: spleen rates varied from 20 to 55. *P. vivax* infections were found in the elevated parts of the island. Great variations of endemicity were found in the island Grande Comore: variations determined in part by the nature of anopheline breeding places, the most important of which are the tanks providing

the water supplies of villages. The three species of *Anopheles* found were *A. gambiae*, *A. funestus* and *A. mauritanus*, the first two being vectors of malaria. These three species are also found on the adjacent north west coast of Madagascar.

VISWANATHAN D. K. Studies on Malaria in Infants in North Kanara District, Bombay Presidency. *J. Malaria Inst. of India* 1945 June v 6 No 1 1-38 4 charts

The observations recorded were made in Haliyal population 6 448 and Yellapur population 1 926 in the North Kanara District where *A. fluviatilis* is the malaria vector. During the space of one year the blood of 432 infants was examined 1 628 examinations in all. On the average 45 per cent. of the total infant population were examined each month. The results indicate that the transmission season in Haliyal is confined to the four months September to December. In Yellapur transmission occurs throughout the year except during the monsoon months July to October. *P. vivax* and *P. falciparum* infections were equally prevalent. *P. malariae* was much less in evidence than it had been in the previous year when malaria was less severe than in the year of investigation. The parasite density in infants was lower than in children of the 2 to 10 age groups but gametocyte prevalence indicates that infants play an important part in transmission.

Malaria in these two places appears to be responsible for an increase in the number of stillbirths and premature births and for increased neonatal mortality resulting from maternal malaria. It is also an important direct cause of infant mortality. The infant mortality rate of Haliyal was 192 per 1 000 live births.

The author sets out the results of his inquiry in very great detail and discusses at length the value and limitations of such data as he collected in assessing malarial endemicity.

YACOB M. & SWAROOP S. Investigation of Long-Term Periodicity in the Incidence of Epidemic Malaria in the Punjab. *J. Malaria Inst. of India* 1945 June v 6 No 1 39-51 5 charts

In the absence of reliable data as to the causes of death in the Punjab the authors make use of the deaths ascribed to fevers in their elaborate study of malaria periodicity in that Province. Malaria epidemics in the Punjab occur soon after the rainy season and any inordinate increase in deaths ascribed to fevers during the last three months of the year affords in the absence of other unusual epidemics presumptive evidence of excessive malaria mortality. In studying the fluctuations of malaria mortality from year to year use is made of an epidemic figure which is the ratio of the average monthly number of deaths from fevers during October, November and December to the monthly average of fever deaths of April, May, June and July of the same year. In years of low malaria incidence the epidemic figure should approximate unity.

Epidemic figures for 77 years (1867 to 1943) have been studied. A statistically significant decrease of malaria mortality over this period has been demonstrated and there is a strong indication that epidemics of malaria tend to occur after a period of about eight years.

FAUST E. C. Clinical and Public Health Aspects of Malaria in the United States from an Historical Perspective. *Amer J Trop Med* 1945 May v 25
No. 3, 185-201 5 figs. (3 maps & 2 graphs) [41 refs.]

This is an informative and interesting account of the introduction, spread and decline of malaria infection in the United States since infection was introduced with the advent of European explorers and settlers and the importation of slaves from Africa two hundred years ago. There is no indication that malaria existed anywhere in North America before then. In the middle of last century most of the settled part of the United States was highly malarious but even then the hyperendemic centres of infection were in the South. Thereafter with increasing prosperity more intensive cultivation, and greatly reduced cost of quinine the heavily endemic territory began to shrink into the south-east corner of the States. Between 1915 and 1933 there was but little change in the malaria incidence except for the five-to-seven years cycle of revived intensity. The severe economic depression commencing in 1931 was responsible for a great increase in the intensity and distribution of malaria. This stimulated co-ordinated control measures which appear to have been responsible for the remarkable decline in malarial mortality which has been continuous and almost uninterrupted since 1933. This decline has been described by the author in annual reports which have been summarized in this Bulletin.

The malaria situation to-day is appraised and the potential dangers attendant upon the return to the United States of military forces, merchant seamen and civilians from highly malarious regions is discussed. Both *A. quadrimaculatus* and *A. freeborni* have been shown to be capable of transmitting Pacific and Mediterranean strains of *P. vivax*.

An interesting graph shows how completely malaria was controlled among troops in the United States during the recent world war and the remarkable decline in malaria morbidity in the army overseas in 1944 as compared with 1943. Norman White.

BRITISH GUIANA. Report of the Malaria Investigations Service of the Medical Department, British Guiana, for the Half Year July-December 1944
[GIGLIOLI G. Government Malariologist 48 cyclostyled pp. [14 refs.]

This progress report contains a vast amount of tabulated information concerning spleen and parasite rates in many parts of British Guiana, and the distribution of *Anopheles*. The special report on the incidence and distribution of malaria throughout the colony which is in course of preparation, will be of great interest. [The Report for 1943 was summarized in this Bulletin 1945 v 42, 614]

A survey of the Corentyne Coast was carried out in September and October 1944. Malaria endemicity here is low. Of 1163 children examined only 1.3 per cent. had enlarged spleens. Parasites were found in 10.7 per cent. of 700 children. In the positive blood preparations parasites were few in the majority. Prolonged examination of thick films revealed only one or two ring forms. *A. aquasalis* (*larviculatus*) is very prevalent in this area, and *A. albipennis* also occurs. Neither of these species appears to be of any importance in the spread

of malaria in British Guiana. Wherever human settlements exist livestock is abundant, and both of these species show a marked preference for the blood of livestock. No *A. darlingi* were found on the Corentyne Coast.

An appendix to the report by M. KENNY deals with inadequate screening as an important factor in spreading malaria. At a mining centre on the Berbice River the population lived in screened wooden houses and in temporary open camps. In the screened houses were numerous cracks and other openings in the floors walls and roofs and the doors were often left open after sunset. Hundreds of mosquitoes were captured in the screened houses 83 per cent being anophelines nearly all *A. darlingi*. Blood examination of the occupants showed a parasite rate of 36 per cent and very numerous gametocyte carriers. Oöcyts were found in 88.8 per cent. of the *A. darlingi* examined. After the institution of daily mosquito catches and the treatment of human carriers the percentage of infected mosquitoes quickly dropped to less than one per cent. The imperfectly screened houses had been mosquito traps. Norman White

HENDERSON J. M. A Discussion on Caribbean Malaria Control. *J. National Malaria Soc.* Tallahassee Fla. 1945 Sept. v 4 No 3 189-200 5 figs

This is a short general survey of malaria conditions prevailing in the islands of the Greater and Lesser Antilles and in the Guianas. The author directs attention to the large amount of research work that remains to be done the multiplicity of problems awaiting solution and the opportunities the Caribbean offers to the enthusiastic malariologist. Norman White

CAUSEY O. R. & MELLO G. B. Malaria in the Amazon Valley of Brazil during 1942 and 1943. *Amer. J. Trop. Med.* 1945 July v 25 No 4 323-7 1 map & 1 graph

Hitherto but little information has been published regarding malaria in the Amazon Valley a fact which enhances the interest of this contribution. The Brazilian portion of the Amazon valley elliptical in shape covers 3,800 000 square kilometres. The country is remarkably flat. Belem near the coast is 14 metres above sea level the elevation of Iquitos Peru 3,200 kilometres up the valley is only 100 metres. Much of the land is flooded. The population of about 1,500 000 live mostly near the navigable rivers in huts built in piles above the mud and water in small villages on knolls surrounded by water or in towns on upland plateaux. Rarely do the people attempt to grow their own food there is usually a food shortage with consequent malnutrition made worse by widespread intestinal parasite infestation. There are wet and dry seasons but rain falls in every month. The average annual rainfall in Manaus is 1,995 mm. and in Belem 2,805 mm.

A malaria parasite survey was made in December 1942 a season when malaria rates are expected to be at their lowest. Thick blood films were taken from about 6 per cent. of the population of Belem, from about 20 per cent. of the population of small towns with more than 1 000 inhabitants and from 30 per cent. of the population of smaller towns. The survey was restricted to towns accessible by air boat or train. In all, 19 629 blood smears were examined malana parasites were found in 979 a parasite rate of 5 per cent. For children of the 1 to 9 age group it was 7.1. *P. falciparum* infections numbered 407 and *P. vivax* 573.

The second survey was carried out at the end of the wet season in June 1943 when 27 103 persons from 37 towns were examined. Instead of the expected rise in incidence the survey showed a parasite rate of only 3.3 per cent. This (144)

may be due to the fact that after the first survey large quantities of atabrin were distributed throughout the valley and anti-mosquito work had been started in several localities.

Anopheles darlingi is the chief vector of malaria throughout the valley. *A. aquasalis* another vector is found near the coast. *A. darlingi* is dependent on lakes or ponds for its survival during the dry season. In an exceptionally dry season these may dry up and *A. darlingi* may disappear altogether. There are some malaria free areas which may be so explained. When reintroduced, *A. darlingi* may cause severe epidemic malaria in such places. Norman H Hitt

BRUG S. L. Edo-Erythrocytaire malariparasieten. [Exoerythrocytic Malaria Parasites.] Reprinted from *Nederl Tijdschr v Geneesk* 1941 June 14 v. 85 No. 24 2745-52 2 pls. (1 coloured) & 1 chart. [Numerous refs.] English summary (8 lines)

The paper describes certain intracellular bodies which were found in smears of the lung of a case of general paratyph which was treated by infection with *Plasmodium inax*. Death occurred ten days after the intravenous inoculation of the parasites and six days after the first appearance of these in the patient's blood. They were also present in the blood at the time of death. A post-mortem examination was made two days after death the body having been kept meanwhile in the cold chamber. Smears were made from a number of organs but it was only in a smear of the lung that anything resembling exoerythrocytic developmental forms of the malarial parasites was found. Three such forms illustrated in a coloured plate and in microphotographs were found, all within cells of the endothelial type. The smallest form was a darkish blue body 3-4 μ in diameter containing four large and three small red-staining masses. It lies in the cytoplasm of a cell about 20 μ in longest diameter. The other two forms which are in somewhat larger cells are of a different nature. They were both found in the same microscopic field. The cytoplasm of each cell is dotted, over the greater part of its extent by red-staining masses some of which are the size of those in the small structure first described others are larger and some are smaller. The cytoplasm of the cell is not uniform, areas of dark blue being interspersed with less deeply staining areas. In some cases a darkish blue ring is associated with one of the red masses giving a resemblance to a malarial ring. The number of red masses in each cell: 40 to 50.

The question asked by the author is: are these appearances due to the presence in endothelial cells of malarial parasites or are they the result of cell metabolism? It is remarkable that the three forms described are the only ones seen in all the films examined after many hours of search, and that the two large ones were in the same field. In the larger forms there is no clear demarcation between parasite and cell but this might be due to the fact that segmentation into separate merozoites had already occurred and that their outlines are somewhat obscured—a not unusual appearance in the case of the multiple infection of the cytoplasm of large cells by small parasites. It is perhaps a coincidence if the red bodies are nuclei of merozoites that both the larger cells contain parasites in the same stage of development.

However this may be it is clear that the illustrations bear a striking resemblance to appearances which may be seen in smears of organs containing the exoerythrocytic forms of bird malarial parasites. [The reviewer has re-examined certain of his own films which show these developmental forms and he has to admit that had the forms depicted by the author occurred in these films he would not have hesitated to call them exoerythrocytic forms but this is in films in which many of the parasites show a clear demarcation between

the cell cytoplasm and that of the parasite so that the occurrence of others in which this demarcation is less clear would not be remarkable. A point worthy of note is that in the cytoplasm of the cell containing the small parasite there are two or three red bodies which cannot be of a parasitic nature though they bear a resemblance to the red bodies in the other two cells. A resemblance of certain blue areas to malarial rings has been mentioned but malarial merozoites in endothelial cells are not of the ring form which is the stage adopted only after invasion of the red blood corpuscle. On the whole therefore the reviewer agrees with the author that the structures which are the subject of his paper bear a resemblance to exoerythrocytic forms of bird malaria but that it is impossible to assert dogmatically that they are the corresponding stages of development of *Plasmodium vivax*. The author is to be congratulated on his exhaustive search and on the coloured drawings which illustrate his paper and which are undoubtedly faithful representations of the cells they depict.]

BOYD M F On Difficulties arising in the Experimental Propagation of *Falciparum Malaria*. *Amer J Trop Med* 1945 July, 25 No 4 293-306

Plasmodium falciparum has been used at the Florida State Hospital since June 1932 largely for the inoculation of coloured patients. The continued propagation of this species by natural passage has proved much more difficult than that of *P. vivax*. Breaks from inoculation failures have occurred in all strains used. In a closely reasoned paper the author analyses the conditions in which these difficulties have arisen.

Failures to infect have occurred though the mosquitoes used were subsequently shown by dissection to have been infected. The presence of sporozoites in mosquitoes that fail to infect indicates that the gametocyte level in the patient from whom the mosquitoes were infected is not a factor. Resistance of the patient has not often been responsible for failure as was shown by the results of subsequent reinoculations. Increasing age of sporozoites (the period elapsed since the completion of the extrinsic incubation period) has been associated with an increasing proportion of failures but failures have occurred with quite young sporozoites. It would appear that the recent ingestion of quinine by the patient on whom the mosquitoes are infected may impair the vitality of the resulting sporozoites.

When some of the strains used were propagated by intravenous inoculation of infected blood their capacity for producing gametocytes deteriorated, sometimes suddenly sometimes gradually. The phenomenon is not attributable to the resistance of the patient or to the administration of quinine. The deterioration persisted through subsequent passages.

A summary does small justice to this paper

WATSON R B Observations on the Transmissibility of Strains of *Plasmodium vivax* from Pacific War Areas by *Anopheles quadrimaculatus*. *Amer J Trop Med* 1945 July, 25 No 4 315-21

Norman White

Six strains of *P. vivax* were obtained from soldiers who had presumably acquired their infections in Pacific war areas by injecting their blood into patients requiring malaria therapy. Morphologically five of these strains differed in no way from the indigenous McCoy strain in general use for treatment but the ring forms of one strain resembled *P. falciparum* trophozoites. The subsequent development of amoeboid forms revealed their identity. Some of the patients with histories of previous *P. vivax* infections offered considerable resistance to the Pacific strains four patients being refractory

[April, 1946]

Tropical Diseases Bulletin

A. quadrimaculatus were fed on these patients with Pacific infections. Sporozoites were found in mosquitoes fed on patients infected with three of the six strains. The failure of three strains to infect mosquitoes may have been due to the climatic conditions prevailing at the time of experiment. It was excessively hot and dry, temperature 84°F and relative humidity 53 to 56. Sporozoite transmission of three strains was successful. In some cases mosquitoes were infected, though microscopic examination revealed no gametocytes at the time of the infective feed.

It is concluded that some at least of the Pacific strains of *P. vivax* can be transmitted by *A. quadrimaculatus* which seems to be, however, a somewhat less efficient vector of these strains than it is of the McCoy strain.

Norman White

WATSON R. B. On the Probability of Soldiers with Pacific *Plasmodium vivax* Malaria Infecting *Anopheles quadrimaculatus*. J. National Malaria Soc. Tallahassee, Fla. 1945 Sept. v. 4 No. 3 183-8.

Batches of 25 newly emerged *A. quadrimaculatus* were applied to patients with *P. vivax* infections, acquired in the Pacific war area, without regard to gametocyte levels. After incubation for 15 days in an air-conditioned room these mosquitoes were examined for salivary gland infection. For 1428 mosquitoes fed on 117 cases (87 patients) the infection rate was 11.8 per cent. The highest infection rate was obtained in mosquitoes which had been fed on patients with parasite relapses without fever. Individuals experiencing their 8th to 15th relapses were twice as likely to infect mosquitoes as were individuals with earlier or later relapses.

CRUCA, M. BALLET L. CHELAKESCU M. & CRISTESCU A. Capacité d'infection du sang des porteurs de gamétocytes de *Plasmodium falciparum* pour *Anopheles maculipennis* (1. atroparvus) [Infective Capacity of *Plasmodium falciparum* Gametocyte Carriers for *Anopheles maculipennis atroparvus*.] Reprinted from Bull. Sect. Sci. Acad. Roumaines Bucharest. 1942, v. 25 No. 2, 98-102.

Thirty-six *P. falciparum* gametocyte carriers were used for the infection of laboratory bred *A. maculipennis atroparvus*. Twenty-three of these patients had been infected with virulent blood, 9 had been infected with sporozoites and 4 were cases of natural infection. The strain used for the infection of 32 patients had been kept going for 14 years in the malaria-therapy station. The researches show that 50 per cent. of these gametocyte carriers were incapable of infecting a lot of mosquitoes in the conditions of the experiment (one infecting feed only). Two cases on which mosquitoes were fed 10 times show the importance of the number of infecting feeds in producing infection. The infective power of the blood is independent of the manner in which infection was contracted (virulent blood or sporozoites).

Three of the four gametocyte carriers who had naturally acquired infections successfully infected mosquitoes, a very much higher rate of infectivity than that shown by patients infected with the laboratory strain. The vitality of the gametocytes of these naturally acquired strains appeared to be much higher than of those of the therapy strain.

Norman White.

GARNHAM P C C The Role of *Anopheles pharoensis* Theobald in the Transmission of Malaria in Kenya Colony Ann Trop Med & Parasit 1945 Oct. 10 v 39 No 2, 63-5

Anopheles pharoensis is a carrier of malaria in Egypt the Sudan Uganda the Belgian Congo and Southern Nigeria in Egypt it is an important carrier in Northern Nigeria and Kenya no infections have been found also in overgrown drains and streams. Adults are rarely found in large numbers in human dwellings At Kisumu where the observations recorded were carried out, they formed from 0.7 to 4 per cent. of the total anopheline day catches in huts for night catches the percentage was 10 They mostly enter huts between midnight and dawn. The salivary glands of 1,334 female *A. pharoensis* and 33 midguts were examined. Neither sporozoites nor oocysts were found. The species feeds on man the stomach contents of 10 engorged females all gave positive precipitin reactions with anti human serum The maxillary index of local specimens was 14.6 which suggests zoophilism. The length of life of the species is sufficient to develop infection. The author suggests that where *A. pharoensis* is an important vector of malaria, a variety of the species and not the type-form is concerned.

Norman White

VINCKE I PARENT M BERTEAUX M & DE MEULENAERE J Note sur la biologie de *Anopheles duren* Edw [A Note on the Biology of *Anopheles duren* Edw] Bull Ass Congolaise des Anciens Etudiants de l'Université de Liège 1945 Oct No 5 30-39 1 chart.

Anopheles duren is a common day biting mosquito near Elizabethville in the Belgian Congo It is not found at all in human habitations but is commonly captured among trees near water Biting takes place throughout the hours of daylight but ceases completely at nightfall other species for instance *A. funestus* were observed during the same investigation to bite almost entirely by night.

Dissections were made of 736 adult *A. duren* some on the day of capture some after five days captivity Approximately 9 per cent were infected with malaria parasites most of them having salivary gland infections Larval breeding places are described. Shaded sections of rapidly running streams are the most important. Both larvae and adults are commonest in January and February and scarcest from March to September

WEATHERSBEE A A. & BOHART G E. Observations on the Nocturnal Activity of *Anopheles* and certain other Mosquitoes in Eastern Puerto Rico. Puerto Rico J Pub Health & Trop Med 1944 June v 19 No 4 626-34 1 chart. [Spanish version 635-42.]

Three experiments were conducted in an attempt to determine the time of greatest activity of mosquitoes in an area of Eastern Porto Rico Horse baited traps were established in three localities and hourly collections were made from them from 5 p.m. until morning The first experiment ran from October 30th to November 10th 1942 the second from November 18th to 29th 1942 and the last from January 19th to 30th, 1943 Three species of *Anopheles* were taken *A. albimanus* (1,330) *A. grahami* (347) and *A. vestitus* (32) There were also five species of *Culex* three *Aedes* two *Psorophora* and one *Democrocid*

The hourly figures are tabulated and show that *Anopheles albimanus* was more active between 8 p.m. and 3 a.m. than during either the earlier or later hours and that the peak time of entry lay between 10 p.m. and 1 a.m. The numbers of the other anophelines do not indicate any pronounced peak of activity.

The common mosquitoes *Culex bahamensis*, *nigripalpus*, *quinquefasciatus* [fatigans], *Aedes taeniorhynchus* and *Psorophora ferox* readily entered the traps at all hours of the night. H. S. Lesson.

RUBENSTEIN, A. D., SHULMAN, M. H. & MERRILL, D. The Hazard of Transfusion Malaria after the War. *New England J. of Med.* 1945 Aug. 23 v. 233 No. 8, 234-7.

Since 1929 twelve cases of post transfusion malaria have been reported in Massachusetts. On the assumption that the chance of such happenings may be increased in the future owing to the greater number of potential donors who have served in malarious regions the authors give details of the twelve cases that have occurred to emphasize the risk of post transfusion malaria. Of the 12 infections 9 were due to *P. malariae*, 2 to *P. vivax* and one to an undetermined species. The interval between the transfusion and the onset of symptoms varied between 10 days (*P. vivax*) and 111 days (*P. malariae*). The time elapsed since the donor was last in an endemic malaria region was determined in 5 cases: the longest period was 27 years, the shortest 12 years. Attempts to demonstrate malarial parasites in blood smears of the donors were made in 7 cases but were successful in only two. Norman White

TALICE, R. V. & MACKINNON, J. E. Paludismo accidental por transfusión [Transfusion Malaria. *Arch. Uruguayas de Med. Ciruj. y Especialidades* 1945 Nov. v. 27 No. 5 473-81. 29 refs. English summary.]

"Two accidental cases of transmission of malaria by transfusion of whole blood are recorded.

Both cases were produced by *Plasmodium malariae*.

One of the donors acquired malaria in Africa 9 years before and the other in Italy 7 years before.

"The infective area of malaria endemicity does not reach the Republic of Uruguay. Consequently in order to avoid accidental transmission of malaria the authors emphasize the advice and conclusions given by Hutton and Shute which may be easily accomplished in Uruguay: that only donors who have never left the country should be used.

CIUCA, M., BALIU, I. & CHELARENCO, M. Contribution a l'etude de l'immunité dans l'infection paludéenne expérimentale. Observations recueillies sur 41 sujets immunisés. Contribution to the Study of Immunity in Experimental Malaria Infection. Observations on 41 Immunized Individuals. Reprinted from *Arch. Roumaines Path. Expér. et Microbiol.* Bucharest, 1943 Jan. Dec. v. 13 Nos. 1/2, 45-122, 41 figs. [111 refs.]

The receipt of this interesting study, admirably produced, affords welcome evidence that the scientific work of CIUCA and his colleagues triumphantly surmounted difficulties imposed by war conditions and has been most profitably carried on.

The paper opens with a useful summary of contributions to the literature of acquired immunity against human, bird and monkey malaria. The 111 references in the bibliography are an indication of the comprehensiveness of

this summary [Some recent work was evidently inaccessible to the authors for example BOYD & KITCHEN (1943) this *Bulletin* 1943 v 40 818 is not quoted]

The observations recorded relate to 41 patients who after having been submitted to malaria therapy were kept under control for from 4 to 14 years. They were immunized by repeated inoculations of virulent blood or more rarely of sporozoites. After the period of immunization inoculations were suspended for some years during which time monthly examinations of blood were made. The duration of immunity was gauged either by determining the persistence in the body of parasites by transfusion of blood into a susceptible individual, or by a direct test of the immunity by a fresh injection of virulent blood.

P. malariae confers a more lasting immunity than the other two species of human plasmodia. The persistence of an immunity against *P. malariae* in the absence of parasites from the body detectable by transfusion certainly does not rule out the possibility of a humoral or cellular immunization. In the immunity conferred by *P. vivax* the rôle of preimmunization is more in evidence but in 3 of 14 of the cases recorded immunity persisted though no latent infection could be demonstrated. When the higher frequency of positive transfusions in *P. vivax* infections is considered it must be remembered that the patients were not protected from possible fresh natural infections.

From the point of view of efficacy and duration of immunity conferred by repeated inoculations *P. falciparum* comes last. The severity of this infection necessitates earlier antimalarial treatment after the first inoculations. The infection is of shorter duration than the other two and there is therefore a shorter antigenic saturation of the organism. All the same a certain resistance persists in patients immunized with *P. falciparum* inoculations as evidenced by the fact that spontaneous recovery may take place from infection given several years later.

HUNTER T A A Fever in a Hyper-Endemic Malarial Area. A Critical Analysis of 2,913 Cases. *Indian Med Gaz* 1945 May v 80 No 5
Norman White

A forward Treatment Unit in one of the most malarious areas of the Assam Burma border in the height of the transmission season received up to capacity all cases of fever British and Indian in which no definite diagnosis had been made. Diagnosed cases of malaria were also received but these were few in number. There were in all —

Proved malaria Clinical malaria Not malaria	British	Indian	Total
	643 41 177	1 563 45 444	2,206 (76%) 86 (3%) 621 (21%)

The author protests against the diagnosis of clinical malaria and the commencement of antimalarial treatment before diagnosis has been confirmed. Of the cases of clinical malaria admitted as such not more than a sixth eventually justified that diagnosis. The facile diagnosis may be dangerous in this series five cases of pneumonia were overlooked by a too easy resort to it. Severe types of malaria are relatively uncommon 2.4 per cent. in this series and fulminant types are rare. In all severe cases parasites were plentiful in the peripheral blood. No evidence was forthcoming of the existence of that

"bogey man of the medical officer" the cerebral case of malaria with persistently negative blood slides. The thick drop method of blood examination is very sensitive. In the series of cases reported, parasites were found on the first examination in 81 per cent. of British cases and in 90 per cent. of Indian cases on second examination, 12 hours later parasites were found in a further 8 and 6 per cent. respectively. There is moreover in military practice an important practical objection to the diagnosis of malaria on insufficient grounds. A patient suffering from malaria is absent from duty for 15 days the average non-malaria patient in this series was fit for duty again within the week.

The percentage incidence of species of plasmodia in this series were —

	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. malariae</i>	Mixed
British troops	30	64	1	6
Indian troops	43	47	1	9

Most British troops had been taking mepacrine as a suppressive most Indian troops had not. This may have been a factor in determining the greater relative prevalence of *P. falciparum* among Indian troops.

In nearly two-thirds of the malaria cases the spleen was not palpable. The spleen rate was higher among Indians.

In 70 cases in which a suspicion of malaria persisted after three negative blood examinations, adrenaline injections were used as a result parasites were found in seven patients. Adrenaline is a useful diagnostic aid. Sternal puncture, a simple procedure was used 20 times. It was not useful as an aid to diagnosis. Spleen puncture was performed three times. It revealed one *Leishmania donovani* infection and one mixed *P. falciparum* and *P. vivax* infection. The procedure is, of course, not suitable as a routine diagnostic measure.

Only eight British and four Indian patients developed cerebral symptoms. There were no algid cases and there were no deaths. A dose of quinine was given intravenously without delay to all patients with *P. falciparum* infections who had symptoms of any degree of severity or in whose blood there was high parasite density.

BYSTROV P. V. [Malignant Fulminating Tertian Malaria, according to Observations of Tambov Pathological Department.] *Ved. Parazit. & Parazit. Dis. Moscow* 1945 v. 14 No. 2, 21-5. (In Russian.)

The author in 1927 was the first to draw attention to the occurrence in the Soviet Union of a fulminating deadly type of benign tertian malaria, affecting chiefly children. Since then outbreaks of this form of malaria have been regularly recorded. This *Bulletin* 1943 v. 40 436-688. 1944 v. 41 257-823. In the present paper the author records post mortem observations on 100 fatal cases of *P. vivax* malaria, carried out by him in the course of the last 20 years, at the prosectorium of the Tambov hospital. Outbreaks of this form of malaria occur regularly every year in the spring (March, April, May) the majority of cases being in children between the ages of 4 and 16 though in seven cases the victims were adults.

The clinical picture was similar in all known cases. The majority had previously suffered from malaria, and usually the attack which culminated in death was the second one. This attack—which was accompanied by repeated vomiting followed by loss of consciousness, convulsions and death—usually started suddenly and lasted only several hours. In all cases the diagnosis was confirmed

by the finding of typical *P vivax* in the blood and organ smears the predominant stages being schizonts. The histopathological picture revealed no special features. In distinction to the comatose form of malignant tertian malaria, the brain never showed any macroscopic evidence of pigmentation. Among the characteristic changes the author notes (1) enlargement of the spleen (2) cerebral oedema, and (3) increased intracranial pressure. Microscopical examination reveals a moderate number of parasites and slight pigmentation chiefly in the spleen and liver. The enormous accumulations of these elements, characteristic of malignant tertian malaria, are never observed.

The author attributes the grave symptoms and fatal termination in this form of malaria to an acute cerebral oedema accompanied by increased intracranial pressure which leads first to irritation and finally to paralysis of the nerve centres. This effect may be due both to mechanical and chemical causes, while the oedema itself is visualized as a local allergic reaction on the part of the nervous tissue as the result of sensitization by the products of decomposition of foreign proteins provided by the parasites

COGGESHALL, L. T. *Malaria and Filariasis in the Returning Serviceman. The Ninth Charles Franklin Craig Lecture. Amer J Trop Med* 1945 May v 25 No 3 177-84

The information in this lecture is based on observations of more than 3 000 service men returned from overseas in the Marine Barracks Klamath Falls Oregon. Most had acquired malaria in the Pacific war area. The records show that initial infections had frequently been with *P falciparum*, but only *P vivax* infections were found at this station. Three men, who had been admitted for filariasis experienced their first malarial attack on the station where there is no possibility of local infection. In one of these cases eight months had elapsed since the man had been in an endemic area and had discontinued suppressive mepracrine. Infections with Pacific strains of *P vivax* are very prone to relapse. Fifty-seven per cent of the men under observation had had more than 14 acute attacks some had had as many as 40. The recrudescences have a certain rhythm many men could predict within a week when the next attack would occur. There was a remarkable absence of malarial cachexia. Splenomegaly was noted in less than 5 per cent. of the men even after 20 to 30 recrudescences. Immediately after the acute attack spleens were palpable in about 8 per cent. Anaemia was conspicuous by its absence after six weeks at the station (the altitude of Klamath Falls is 5 000 feet) the average red blood count was 5,300 000. Except for persistent headache in some cases there was no disability between acute attacks of fever. Finally Negroes who are very refractory to U.S. strains of *P vivax* are very susceptible to Pacific strains.

The men were put on full duty military training recreational, educational and vocational activities. This was regarded as important. Physical fitness was quickly regained and the development of hospitalitis avoided. Even South Pacific malaria is a self limited disease. The rate of recrudescence had a downward trend in the malaria that was still active after three years from inception.

There was a large group of men with *Wuchereria bancrofti* infection which in 96 per cent. of cases had been contracted in the Samoan group of islands. The incubation period from the first possible exposure to infection to the appearance of initial symptoms averaged nine months. The clinical signs were lymphoedema lymphadenopathy and lymphangitis—in the neck (2 per cent.) upper extremities (30) lower extremities (9) scrotum (1) spermatic cords (15) and testes (18 per cent.) The manifestations were very mild. Microfilariae were not found in any man in the station occasional eosinophilia was the only abnormal

finding on blood examination. Temperatures were normal, and a chronic cough was the only symptom. Occasionally the oedema, lymphangitis and muscular soreness flare up but for a few days only and attacks become less and less frequent. It has been necessary to admit to hospital only one man in 800 for filariasis. The psychic element in these cases is prominent and patients need reassuring—all accumulated evidence shows that filariasis will not result in permanent disability in such cases. Mental and physical rehabilitation of these cases is most important to avoid unnecessary invalidism.

There is no likelihood that filariasis will gain a foothold in the United States. [See also ZELIGS, this *Bulletin* 1946 v. 43 53] Norman White

KAPLAN A. Recurrent Headache resultant from Malaria. *J Amer Med Ass* 1945 Oct 27 v. 129 No. 9 612-13

An American Marine who had apparently been exposed to malarial infection in the Pacific area between April 1942 and the time of his admission to the ship's sick bay in December 1943 complained of severe occipital headaches of three weeks' duration which prevented sleep and had led him to drink alcohol to excess in the hope of getting some relief.

Very thorough physical and psychiatric examinations, radiography of the skull, Kahn tests of the blood and cerebrospinal fluid, chemical examination of the blood and cerebrospinal fluid, the extraction of two lower molar teeth, all led to no diagnosis during two months of hospital study; he was discharged unimproved and at his own request returned to duty. No examination of blood films for malaria parasites was made.

His headaches continued and prevented sleep and after trying to carry out his duties for five days he was again admitted for further study. This produced no diagnosis except on of psychoneurosis by the psychiatrist who reported fully on his mental state. Again no blood films were examined. After two months he was admitted to a hospital on the mainland and was again submitted to exhaustive physical and psychiatric examination together with laboratory studies, but still no examination of blood films was made. The psychiatrist reported that the patient had a desire to do his duty but showed lack of energy and determination—he appeared to be unhappy.

After a month's leave he was allowed to return to duty and managed to carry on for nine months in spite of recurrent headaches. He was then returned to the Pacific area where his headaches continued for eight months and he steadily lost weight for six months. He was admitted to the hospital complaining that his headaches had been very severe for the last month and that he had had chills and fever for 10 days. A blood film showed *Plasmodium vivax*. Treatment with quinine and atabrine cured the chills and fever and his headaches completely disappeared—for the first time during some years.

The author comments that the experience he describes is not altogether unusual and that malaria in the Pacific area is a common disease.

J. F. Corson

NAGLEY L. Probable Relapse of Malignant Tertian Malaria after Thirteen Years. *Lancet* 1945 Dec. 15 773-4

This is a report of a most unusual case. The patient had been a soldier in India from 1919 to 1928 when he returned to England and since then he has not been out of the British Isles. He had malaria in India in 1928 and a possible relapse in 1932 which was "cured" with one dose of quinine. Thereafter he remained in good health till April 1935 when he fell ill with jaundice, vomiting, bloody diarrhoea and daily shivering attacks. Blood examination

revealed very numerous ring forms of *P. falciparum* and crescents. He recovered. It is incredible that he should have been infected with *P. falciparum* in England thus early in the year. He had never been treated with malaria therapy nor had he ever had a blood transfusion. It is difficult to escape the conclusion that the attack was a relapse 17 years after infection.

Bissow H. Über Psychosen nach Malaria. [Malarial Psychoses.] *Allgemeine Zeitschr. f. Psychiatrie u. ihre Grenzgebiete* 1944 Sept. 25 v. 123 Nos. 3/4 235-77 [18 refs.]

More than half of this long article consists of a detailed description of the symptomatology of 14 cases of malarial psychoses of which 10 were associated with benign tertian infection three with malignant tertian and one with a mixed benign tertian and malignant tertian.

All the patients were being treated or had been treated with the standard course of atabrin and plasmoquine but the author does not consider that the treatment was responsible for the illness.

No indication is given of the total number of cases of malaria among which the psychoses occurred except that the author refers to an extensive experience of great epidemics during the war and mentions that the condition is relatively uncommon.

In five cases the onset was during a febrile paroxysm in eight it occurred one to nine days after defervescence and in one it was 20 days later. The manifestations were very varied including mania anxiety depression hallucinations delusions and in three cases suicidal tendencies.

The duration was very variable but even in prolonged attacks the prospect of complete recovery is considered to be good.

Menon T. B. & Velliah G. D. Acute Polyarteritis Nodosa in a Case of Malaria. *Indian Med. Gaz.* 1945 Sept. v. 80 No. 9 452-4 7 figs on 1 pl. [12 refs.]

Babin Frances & Dulaney Anna D. Complement Fixation in Malaria and Syphilis. *Amer. J. Hyg.* 1945 Sept. v. 42 No. 2 167-73 3 figs

The authors have found that not only may malaria be a cause of false positive complement fixation reactions for syphilis but that syphilis may be a cause of false complement fixation reactions for malaria when a phosphate buffer extract of *P. knowlesi* is used as antigen. The human material available for study consisted of 200 patients with relapsing *P. vivax* infections who were clinically and serologically negative for syphilis. 408 sera giving positive Kahn reactions obtained from the laboratory of a State Health Department and 22 syphilitic patients with induced malaria. Sera were collected at intervals of 3 to 5 days from the malaria patients. 1851 samples were thus collected and on each sample complement fixation tests for both malaria and syphilis were performed simultaneously. Of these 129 gave positive Wassermann reactions (7 per cent) and 112 of these 129 sera also gave positive results with the *knowlesi* antigen (87 per cent). Of the 1722 sera that gave negative Wassermann reactions 1105 (64 per cent) gave positive malaria reactions. Most of the positive Wassermann reactions in malaria patients occur from 6 to 10 days after a malaria attack.

Of the 408 syphilitic sera taken at all stages of syphilis infection 14.5 per cent. gave strongly positive reactions and 6.8 doubtful reactions with the *knowlesi* antigen. High titred syphilitic sera give a larger number of these false reactions than do low titred sera.

In the 22 syphilitic patients with induced malaria the malaria complement fixation test became positive at the time the first positive blood film was observed, or shortly after and the titres followed the rise and fall of the parasitaemia. Eighteen of these 22 patients showed a rise in Wassermann titre coincident with the rise of the malaria complement fixation titre. The relation between fluctuations in the malaria and syphilis complement-fixation titres was striking

ROBINSON H. M. Jr & MCKINNEY W. W. The Effect of Vivax Malaria on Spinal Fluid and Blood Serologic Test for Syphilis. *J Amer Med. Ass.* 1945 Nov 3 v 129 No. 10 667-8 1 chart.

One hundred soldiers who were suffering from *P. vivax* malaria, with parasites in the peripheral blood, and who were non-syphilitic, were arbitrarily selected for these studies. They had all been in a malarious region for several months and had been transferred to a malaria free district three months before the investigation began. Nine were experiencing their first attack of malaria the others had had from one to sixteen previous attacks. Lumbar puncture was performed and blood taken for serological tests within 5 days after the diagnosis of malaria was made. If the blood test was positive or doubtful the test was repeated at weekly intervals till a negative reaction was obtained. The standard three-tube Kahn flocculation test was performed on all blood specimens and the spinal fluid was examined with the standard Kahn test Pandy and cell count. The spinal fluid Kahn reaction was negative in all cases. In two cases the Pandy was reported as "a trace". The cell count was within normal limits in all. The blood serological test for syphilis was positive in 33 patients doubtful in 11 and negative in 56. Two of the patients with positive reactions were lost from observation. Of the remainder 26 gave negative reactions after four weeks and all had become negative after 10 weeks. All patients had been put on mepacrine therapy as soon as the diagnosis of malaria was made. There was no apparent correlation between the number of attacks of *P. vivax* malaria suffered and the development of positive serological reactions for syphilis.

FENTON J. C. B. & LIXES J. A Staining Method for Malaria Parasites in Thick Blood-Films. *Trans. Roy Soc Trop Med & Hyg.* 1945 Sept., v 39 No. 1 87-90

The staining method described is a modification of the now well-known Field procedure whereby a thick film is dehaemoglobinized during the staining process which is completed by immersion for 10 to 15 minutes in a corrective Leishman solution. It is claimed that the method ensures optimal staining results for the demonstration of malarial parasites. Those who wish to try the new method must consult the original article for details of the technique and method of preparation of the three staining solutions used.

DAS GUPTA, B. M. LOWE, J. & CHAKRAVARTI H. M3349 (Paludrine) in the Treatment of Human Malaria. *Indian Med Gaz.* 1945 May v 80 No 5 241-5.

This study of the value of paludrine an antimalarial compound prepared by Imperial Chemical Industries in the treatment of malaria, was designed to

determine the toxicity of the drug and the relapse rate after treatment. The difficulty of keeping general hospital patients under observation sufficiently long to determine the relapse rate prompted the selection of malaria patients in the Narkeldanga Relief Camp for Sick Destitutes for the trial. Thirty-one such patients were admitted into the Tropical Diseases Hospital and 75 were treated in the Camp. It is rather unfortunate that patients in such bad physical condition should have been selected.

The drug was put up in tablets each containing 0.2 gm. The dose recommended in the control of attacks of malaria was three tablets a day for seven days. The occurrence of two deaths of patients under treatment in hospital early in the trial caused the subsequent dosage to be reduced to two tablets a day. The two patients who died were both infirm men of 60 and 65 years of age, their weights were 86 and 85 pounds respectively. Whether the toxicity of the drug contributed to death seems to be doubtful.

The authors conclude that paludrine has an action comparable to that of quinine and mepacrine in both *P. falciparum* and *P. vivax* infections, fever being promptly controlled and parasites disappearing from the peripheral blood. In four cases of *P. malariae* infection the action was less marked.

Of 60 patients treated and kept under observation for several weeks, 18 had a clinical relapse from 19 to 58 days after treatment, and seven had a parasitic relapse without fever. The early relapse rate was thus 30 per cent. Some of these relapses may well have been fresh infections for most of the work was done in a camp in a highly malarious area in the middle of a malaria epidemic!

Of 51 patients with *falciparum* infections and observed for several weeks there was no *falciparum* relapse, but 8 had a return of fever with *P. vivax* in the blood.

In persons in reasonable physical condition symptoms of intolerance to the drug (such as nausea and vomiting) are slight and present no great difficulty. In persons with complicating diseases, particularly respiratory diseases, the danger of toxic effects is much greater. Three deaths occurred among patients being treated with two tablets a day. Thus there were five deaths in all, but in only one of these was there no serious complicating disease.

Norman White

STOKES J. F. The Treatment of Relapsing Malaria. *J. Roy. Army Med. Corps* 1945 Aug. v. 85 No. 2 75-80 1 fig. [13 refs.]

The drain on man-power of continually relapsing malaria is more serious than the occasional death from cerebral malaria. The relapse rate in a series of British patients of the 14th Army known to be relapsing was 64.7 per cent. over a period of 11 weeks. The author discusses various views that have been put forward regarding the pathogenesis of relapse. In a search for a method of reducing the relapse rate a trial was made of urea stibamine. This was prompted by certain analogies between kala-azar and malaria, but more by two cases that had come under observation. These were two Indians who were suffering from both kala-azar and relapsing malaria, neither had a malaria relapse while undergoing prolonged treatment with urea stibamine.

Two series of observations were carried out: the first on Indian soldiers, 48 experimental and 50 controls, and the second on British troops, 52 experimental and 52 controls. The observations were made in malaria-free localities.

Every patient received the standard malaria treatment: quinine 10 grains thrice daily for 2 days; mepacrine 0.1 gm. thrice daily on days 3 to 7; pamaquin 0.01 gm. thrice daily for British troops and twice daily for Indian troops on days 10 to 14. The experimental patients received doses of urea stibamine

on the 15th, 17th, 19th and 21st days of 0.05, 0.10, 0.15 and 0.20 gm. respectively. The corresponding doses for Indian troops were 0.025, 0.05, 0.10 and 0.15 gm.

The relapse rates for the control and experimental groups of British troops were almost identical over a period of 91 days: 70.6 and 70.2 per cent. On the other hand urea stibamine appeared to reduce the relapse rate of the Indians who were however observed only for 5 weeks. During this time the relapse rate of the control group was 34 per cent. and of the experimental group 6.25 per cent. But in the experiment with British troops 46 per cent. of the relapses occurred after the fifth week and the author believes that had the Indians been kept longer under observation the relapse rates of the two groups would have more nearly approximated.

The author concludes that urea stibamine is unable to influence the course of relapsing malaria.

PROKOPEAKO L. L. Parasite-carriage of *Pl. vivax* in a New Focus of Malaria subjected to Control Measures. *Med. Parasit. & Parasitic Dis.* Moscow 1945 v. 14 No. 2, 3-13, 4 figs. [In Russian.]

This paper deals with the effect of systematic drug treatment upon the incidence of carriers among patients suffering from benign tertian malaria in a new focus of the disease. The observations were made in three villages of the Moscow province during 1940 and 1941. Both clinical cases and carriers were treated with acrinone mepracrine, the course consisting of three cycles of seven, two and three days respectively, separated from each other by free intervals of ten days each, the daily dose for adults being 0.3 gm. During the entire period of observation the number of cases of malaria with febrile symptoms exceeded that of asymptomatic carriers (249 or 79.6 per cent. and 64 or 20.4 per cent. respectively, out of a total of 313 cases). The effectiveness of the treatment was assessed by comparison of 141 patients who had undergone a regular course of treatment, on the one hand, and a group of 46 treated irregularly on the other hand. In the former group relapses occurred only in 19.8 per cent. while in the latter 26 (i.e. more than 50 per cent.) relapsed. Furthermore in the first group repeated relapses were more frequent, thus 28 patients had 37 relapses comprising 23 acute and 14 asymptomatic cases (carriers). In the second group 26 patients had 48 relapses (27 acute and 21 asymptomatic). It is concluded that properly conducted regular treatment of malaria leads to a marked reduction in the total number of relapse cases, both acute and asymptomatic.

C. A. Hoare

GALUSHEVA O. N. Malaria Treatment by Irradiated Quinine. *Med. Parasit. & Parasitic Dis.* Moscow 1945 v. 14 No. 2, 26-7. [In Russian.]

It has been shown by R. SKIN that quinine irradiated by ultraviolet rays has a more powerful effect upon chabates *in vivo* and a more lasting therapeutic action in bird malaria, than ordinary quinine. In the present paper the author records the results of treatment of human malaria with irradiated quinine. The method of preparation is as follows: 10 per cent. solution of quinine hydrochloride is poured out into Petri dishes and irradiated with a quartz lamp at a distance of 30 cm. for five minutes. The solution is then evaporated in a water bath, and the dry powder is administered in daily doses of 0.3 gm. for four days in succession (five days in the case of malignant tertian malaria) followed by three cycles of three days each, with intervals of four days between the cycles.

Of the 30 patients under this treatment 20 were in the acute stage of the disease with parasites in their blood (17 benign and 3 malignant tertian cases) while 10 had subfebrile temperatures attributed to chronic malaria though no parasites were found in their blood. In the last group irradiated quinine brought about only a temporary reduction of the temperature whereas in the true malaria cases the results of treatment were very promising. As a rule the first dose prevents further paroxysms except in malignant tertian malaria with daily paroxysms. In the latter case febrile symptoms were sometimes observed two or three days after treatment. As regards the parasites these disappeared in 2-3 days in benign tertian malaria while the gametes of *P. falciparum* disappeared after a fortnight. The most important result of this treatment is thus the rapid cessation of attacks of fever and the absence of relapses in patients kept under observation up to eighteen months after a course of treatment.

GOTTFRIED S. P. & LEVINE A. C. Liver Function Studies on Soldiers under Prolonged Atabrine Administration. *J Lab & Clin Med* 1945 Oct v 30 No 10 853-5 [17 refs.]

Fifty Negro soldiers who had been taking atabrine 0.1 gm. six days a week for 18 months were examined. None had had clinical malaria, syphilis, scrub typhus or jaundice. The tests employed were icterus index, urine urobilinogen, fibrinogen, serum cholesterol partition and the oral hippuric acid test. Where the total serum cholesterol values were high, total serum lipid determinations were made. As a check on the fibrinogen results this determination was also performed on 50 other soldiers who had been taking atabrine for only from one to three months.

Several months later bromsulphalein, cephalin flocculation and galactose tolerance tests were performed on 50 more soldiers who had also been taking atabrine for from 20 to 24 months. As a control of the sensitivity of the cephalin flocculation test determinations were performed on 25 soldiers who had been taking atabrine from one to three months.

At a still later date 25 additional bromsulphalein tests were done on soldiers who had been taking atabrine for 30 months.

Plasma fibrinogen was determined colorimetrically. Icterus index was determined by the method of MEULENBACHT (*Deut Arch f Klin Med* 1920 v 132 285), urine urobilinogen by SPARKMAN's method (*Arch Intern Med* 1939 v 63 856), oral hippuric acid test by QUICK's method as modified by KRAUS and DULKIN (*J Lab & Clin Med* 1941 v 26 729 & 1078). Total serum cholesterol was measured colorimetrically and free cholesterol by the method of SCHOENHEIMER and SPERRY (*J Biol Chem* 1934 v 106 745). The total lipid content was measured gravimetrically. The bromsulphalein test was done by injecting 2 mgm. per kgm. of body weight and by measuring the retention at the end of 18 minutes. The cephalin flocculation test was done by HANGER's method (*J Clin. Invest.* 1939 v 18 261) and the galactose tolerance test by the method of JANNEY and ISAACSON (*J Amer Med Ass* 1918 v 70 1131).

Of all the hepatic function tests employed only the hippuric acid test gave results indicative of hepatic dysfunction and then in only very few cases. This by itself was not significant. The conclusion is that no subclinical liver damage could be detected among the soldiers studied.

Norman White

J AMER MED ASS 1945 Dec. 15 v 129 No 16 1091-3 Untoward Reactions attributable to Atabrine.

This report represents the views of a considerable number of U.S. Army medical experts on cutaneous reactions that have resulted from the administration of suppressive atabrine, notably the atypical lichen planus syndrome.

The condition was observed in the latter half of 1943 in soldiers who had been evacuated from New Guinea and adjacent islands. The syndrome has been most commonly seen in this area and in Assam and North Burma elsewhere only few cases have occurred. The incidence of these cutaneous lesions has been low even in New Guinea, and has not constituted an important handicap from the military point of view. Cutaneous reactions have been more frequent in persons who have taken suppressive atabrine in larger doses than the recommended amount 0.7 gm. per week.

It is suggested that the cutaneous reactions attributed to atabrine should be grouped under the heading "atabrine dermatitis complex" and be classified as (a) lichenoid dermatitis (b) lichenoid and eczematoid dermatitis (c) eczematoid dermatitis (d) exfoliative dermatitis secondary to (a) (b) or (c).

Usually the disease is characterized by localized violaceous or erythematous eczematoid plaques on the dorsal surface of hands or feet, side of the neck, or elsewhere followed by generalization of the lesions with subsequent appearance of lichenoid plaques and mucous membrane lesions. A characteristic eczematoid dermatitis has also occurred in persons taking suppressive atabrine. There are bilateral, symmetrical, violaceous-tinged, vesicular eczematoid and oozing plaques on hands, feet, legs and sometimes other parts of the body. Secondary pyogenic infection is common.

The treatment of these conditions depends on early recognition of their nature and discontinuation of atabrine. Whenever possible such cases should be seen by a competent dermatologist and every effort should be made to rule out other aetiological factors. The very much higher incidence in New Guinea and adjacent islands, Assam and North Burma than elsewhere suggests that climatic or other geographical factors play a rôle in causation. Various forms of cutaneous trauma may contribute to the onset and localization of lesions.

An adequate summary of this important paper is not possible. The general statement at the end of the report "for the information and guidance of all concerned," is as follows —

"(1) The military value of atabrine in suppressing vivax malaria and curing falciparum malaria far outweighs untoward effects which have been attributed with reason to the use of the drug.

"(2) Suppressive doses of atabrine greater than 0.7 gm. per week should not be employed routinely. This amount has been shown to provide adequate protection against clinical attacks of malaria provided atabrine discipline is strictly enforced. In clinical treatment of malarial attacks with atabrine, routine dosage † not exceed 2.8 gm. in seven days.

"(3) Atabrine suppressive medication should be discontinued promptly and atabrine should not be given for clinical treatment when persons develop atypical lichen plans, unexplained chronic eczematoid dermatoses, unexplained toxic erythematous eruptions, exfoliative dermatitis, severe leukopenia, agranulocytosis and aplastic anemia, acute hepatitis (not including disturbances believed to be due to malaria) or toxic psychoses which can be reasonably attributed to atabrine after careful clinical study.

"(4) It should be remembered that drugs other than atabrine such as the sulfonamides and arsenicals, may be harmful to persons with the conditions mentioned.

"(5) Caution should be exercised in attributing disease conditions to atabrine until careful and complete studies have been made over a period of time to establish such relationship. Because of the widespread use of atabrine, its administration inevitably coincides with many diseases with which the drug has no connection. Even if a connection is established between atabrine and a given untoward effect, its significance relative to the military value of atabrine requires evaluation. It should be remembered that, since the use of atabrine became widespread, clinical attacks of falciparum malaria have been almost eliminated and deaths from

malaria have been extremely rare There is no question of the general superiority of atabrine over quinine both for suppression and for clinical treatment

WHITEHILL R. Skin Sensitivity due to Atabrine
Dept 1945 Dec v 4 No 6 724-5

An Army nurse had occasional contact with atabrine [mepacrine] during every day She was admitted to hospital on 6th November 1943 with an itching rash on the eyelids. There was no family or personal history of allergy or of skin disease She had used various cosmetics and a hair lotion for some time The rash appeared 3½ weeks before her admission as a small scaly lesion on the lids of the right eye on the left eyelids next day and a few days later a small patch appeared behind the right ear The patches slowly enlarged and the itching interfered with sleep. On admission the skin of the eyelids and behind the right ear showed a scaly erythematous rash and the conjunctivae were somewhat injected. Patch tests with the cosmetics and other substances with which she had had contact gave negative results. She was treated with Burrow's solution [Liquor Aluminii Acetas] diluted 1:20 and on November 20th she returned to duty in the medical ward.

On 24th November the rash reappeared on her eyelids as an erythema with tiny vesicles Patch tests were made with various drugs and all were negative except the test with atabrine which produced a 3+ reaction with erythema and a few vesicles itching beginning within 12 hours. The rash gradually faded and disappeared in two weeks. The nurse was transferred to a surgical ward and had no further attacks

NELSON L. M. Dermatitis from Atabrine
1945 Dec v 4 No. 6 725-7 Bull U.S. Army Med Dept

Two cases of dermatitis in American soldiers apparently caused by atabrine are reported. The first patient developed a pruritic dermatitis about 2 months after he began to take suppressive doses (0.4 gm. a week in divided doses) of atabrine in the summer of 1943 the rash appeared first on his wrists and afterwards in spots all over his body When he stopped taking atabrine in the autumn of 1943 the rash disappeared but returned in the following May 11 days after he again began to take atabrine He was now seen by the author who observed that he had violaceous macular lesions about 5 mm. in diameter on the front of his wrists and upper part of the palms of his hands He stopped taking atabrine and the pruritus disappeared in 3 days For diagnostic purposes he again took 0.1 gm. of atabrine on June 2, 3 and 4 and the same pruritic rash reappeared on June 4 A patch test of atabrine applied on June 5 was negative on June 7

The second patient took atabrine in suppressive doses (0.4 gm. a week in divided doses) during the summer of 1943 until his admission to hospital on October 15 In the last week of September he developed dermatitis on the left ankle and right wrist this was treated with sulphadiazine ointment but the rash appeared on the eyelids and ears and after admission bullae appeared on the arms and legs and a generalized exfoliative dermatitis finally developed. He lost part of his hair and deep depressions formed on the finger nails. He slowly recovered under local treatment in hospital and was discharged on 5th February 1944

He had minor local attacks of dermatitis between February and April and on April 14 he again began to take atabrine as before three days later his

eyes and ears became swollen and he was admitted to hospital and was seen by the author. He then had generalized dermatitis—exudative on the groins, genitalia, popliteal and cubital spaces and ears, oedema of the face, especially the eyelids, follicular vesicles on the arms and thighs and vesiculo-papules over the rest of the body. He gradually recovered under local treatment.

A patch test of atabrine was negative at 48 hours and positive (papulo-vesicular rash) at 60 hours. A patch test with 5 per cent. sulphadiazine in lanoline and petrolatum was positive (vesicles) at 48 hours while a patch test with powdered quinine was negative at 48 hours. A patch test with atabrine done on 8 control persons was negative.

Few cases of dermatitis due to atabrine have been reported. The author saw another case, in a medical officer in 1943 and refers to two cases reported by NOOJIK and CALLAWAY (*North Carolina Med. J.*, 1942, v 3 239).

CHOPRA, R. N. & CHOPRA, I. C. Individual Variations in the Absorption of Drugs from the Gastro-Intestinal Tract. *Indian Med. Gaz.* 1945 May v 80 No. 5 267-71.

A description of the physiology of the various parts of the alimentary tract precedes a discussion of the factors responsible for remarkable individual variations observed in the absorption of drugs, not least of antimalarial drugs. The absorption of drugs is modified in inflammatory conditions of the mucous membrane of the gut, and by hypoacidity which commonly characterizes chronic dysentery and other infections. The rapid passage of meals through the intestinal tract in dysenteries, liver diseases and other conditions hinders absorption. Five illustrative cases are described in which failure of malaria infected patients to respond to the administration of antimalarial drugs was explained by much delayed absorption, as revealed by urine examination.

BOYD, M. F. & KITCHEN, S. F. On the Employment of Quinacrine Hydrochloride in the Prevention of Malaria Infections. *Amer. J. Trop. Med.* 1945, July v 25 No. 4 307-14.

The experiments described were designed to assess the protection afforded by mepacrine against malaria infection. Patients were inoculated by the application of various lots of insectary reared *A. quadrimaculatus* experimentally infected with either *P. vivax* or *P. falciparum*. The patients were white adult males presumably susceptible to infection. The experiments which are described in detail, indicate that the administration of mepacrine, 0.1 gm. six days a week, begun a week before and continued throughout the period of exposure gave complete protection against *P. falciparum* but failed to protect against *P. vivax*. In some instances the small dose of 0.1 gm. on two discontinuous days a week appeared to protect against *P. falciparum* and in one case though parasites appeared in the blood, there was no clinical malaria. Even if the period of administration of 0.1 gm. six times a week be commenced two weeks before and continued to two weeks after the period of exposure to infection *P. vivax* later becomes clinically active after protracted incubation periods.

LEWIS, R. A. & KIRBY, F. W. Suppression as an Adjunct to the Therapy of Malaria in Non-Malarial Areas. *Bull. Johns Hopkins Hosp.* 1945 Sept., v 77 No. 3 211-17.

These observations concern a group of 63 members of the Medical Detachment of a General Hospital, who were suffering from *P. vivax* infections causing

frequent early relapses. The observations were made in an area in which there was no possibility of natural reinfection. The clinical treatment of the acute attack most frequently employed was 2.8 gm. of atabrine during a seven day period. It was found that if the clinical treatment of the recurrence was followed by the administration of 0.1 gm. atabrine daily for two months the interval between relapses was increased from less than six weeks to more than four months and the percentage of relapses was reduced from 80 to less than 50. The less frequent periods of hospitalization resulting from this suppressive treatment resulted in improved morale. Many of the men so treated gained weight notably so in the case of men in whom repeated attacks of malaria and weight loss had been associated. In most cases headache and weakness cleared up but there were exceptions.

BUXTON P. A. Experiments with DDT in Solutions and Emulsions against Mosquito Larvae in West Africa. *Bull. Entom. Res.* 1945 Sept. v 36 Pt. 2, 165-75.

The experiments described were carried out near Takoradi Gold Coast and were designed to assess the relative effectiveness of different preparations containing DDT as larvicides. These were tested against *A. funestus* larvae in ditches about two feet wide separated from each other by ridges some six feet wide in a vegetable garden. These provided good opportunities for repetition and measurement of dose of larvicide per unit area.

An emulsion was made by dissolving DDT in two volumes of lubricating oil (Pool Grade 3) and one volume of Amoa A.S.X. an oil-soluble emulsifier. The DDT content was 5 per cent. by weight of pure DDT. Diluted to 1:10 this makes a very lasting emulsion.

A dieselene solution was made by dissolving a commercial DDT 60 per cent. pure in a locally available dieselene generally a 5 per cent. concentration of pure DDT was used but for putting on very small doses a 0.5 per cent. concentration was suitable.

Preliminary experiments showed that neither kerosene nor dieselene without DDT were larvicidal in doses up to 0.5 cc. per square yard.

The dieselene solution was more effective than the emulsion as is shown in the following table —

Dose cc. 5 per cent. pure DDT per sq. yd.	Emulsion		Dieselene	
	Immediate (kill %)	Lasting (days)	Immediate (kill %)	Lasting (days)
0.01	—	—	100	1-2
0.02	Nil	Nil	80-100	2-3
0.10	Over 80	1-2	100	4
0.50	95-100	7-10	100	6 (several weeks partial)

In shallow water DDT seems to dissolve from oil into water so as to make a larvicidal solution.

The larvicidal effect passes off in a few days even when a high dose (0.10 cc. of 5 per cent. DDT per square yard) has been applied on stagnant water. It is not known what happens to the DDT. A heavy dose (0.5 cc.) after a period of complete kill exercises partial irregular larvicidal effect for as much as four weeks. This action is not explained.

Creatures that prey on mosquito larvae were not destroyed in these experiments. Norman White

CAMBOURNAC, F. J. C. & SIMÕES, J. M. P. Nota sobre alguns ensaios realizados com Neocid e 7013 Geigy contra as larvas de *Anopheles* [Experiments with Neocid and 7013 Geigy as *Anopheles* Larvicides.] *An. Inst. Med. Trop. Lisbon*, 1944 Dec. v 1 No 2 383-92.

Neocid and 7013 are substances allied to DDT (dichlor-diphenyl-trichlor ethane). Neocid is said to have the composition trichlor-4, 4-dichlor diphenylmethane mixed with an inert powder in the proportion of 5 per cent. The composition of 7013 Geigy is not given. The larvicidal action of both these substances was tested against the larvae of *A. maculipennis atroparvus* under natural conditions. They were applied as 1 per cent. mixtures with road dust and in liquid suspension. The amounts of Neocid in suspension were 0.05 gm. and 0.2 gm. per square metre and with dust 0.1 gm. per square metre. The amounts of 7013 used were 0.2 gm. per square metre in suspensions and 0.1 gm. per square metre in dust. On occasion larvae were totally eliminated, but the results were not consistent. Sometimes the smallest larvae appeared most resistant at other times larvae of the later stages. The larvicidal action was of short duration. Norman White

WHITE, R. Senior. House Spraying with D.D.T. and with Pyrethrum Extract compared. First Results. *J. Malaria Inst. of India*, 1945 June v 6 No. 1 83-83.

The locality selected for this experiment is in the hyperendemic Jaypore Hills the malaria conditions in this area have been previously described by the author [this *Bulletin* 1937, v 34, 627]. The three villages referred to in this paper still have very high spleen rates Chatikona 98.0 Jimidiguda 87.8 and Bariguda 92.7 per cent. Jimidiguda, a small village of 48 houses was sprayed with a 5 per cent. solution of DDT in grade III kerosene applied with a De Vilbiss paint gun served by a Kapur hand pressure sprayer at the rate of 1 qt. per 1 000 square feet of wall surface. Care was taken to wet all the wall surfaces including outside verandahs and the roofs as far as accessible. Chatikona was sprayed with pyrethrum insecticide Bariguda was an untreated control. The author's conclusions are as follows—

"(i) D.D.T. at the rate of 1 qt. 5 per cent. solution per 1 000 sq. ft. will prevent infection in the *fevershike*-group in a hyperendemic area, in the cold weather of Southern India, for eight weeks. It acts by reducing density as well as longevity.

"(ii) Pyrethrum spraying, 6 days each week, reduces density and longevity sufficiently to inhibit gland infections. The density reduction is much less than with D.D.T. This is probably due to a certain proportion of the house population leaving before the morning pyrethrum spraying, whereas with D.D.T. it is believed that any specimen which has rested after feeding on a still active treated surface must die.

"(iii) Pyrethrum spraying twice a week has no effective result either on density or on infectivity. As a method of protecting a population exposed to the *fevershike*-group it is useless.

"(iv) Assuming the cost of D.D.T. as stated to be correct (Rs. 3 per lb.), over the two months December to February a period of heavy though not of maximal transmission, D.D.T. is 20 to 25 times cheaper per capita per week than pyrethrum."

COLLIGNON E. La campagne antipaludique de 1944 dans le département d'Alger [The Antimalaria Campaign in the Department of Algiers in 1944] Arch Inst Pasteur d'Algérie 1945 June v 23 No 2 98-110

As in 1943 the malaria campaign in 1944 concentrated on the protection of military forces stationed in the Algiers Department. The antimalaria services of the British and United States armies and of the local government were each responsible for a delimited area. This arrangement only related to measures against the anopheline vector drug prophylaxis being in the charge of each authority as concerned its own personnel.

It was a difficult year for the departmental service. The shortage of anti-malarial drugs prevented their use for prophylaxis. Transport difficulties and the difficulty of recruiting labour of a reliable type were obstacles to the satisfactory execution of antilarval measures. Nevertheless the malarial situation was not unsatisfactory there were no important epidemic manifestations and climatic conditions limited anopheline breeding places. Indices of infection were if anything somewhat lower than in the two preceding years.

INCKE I with PARENT M. Un essai de lutte antimalarienne spécifique à Stanleyville [Control of Malaria in Stanleyville by Species Sanitation.] Reprinted from Bull Ass des Ingénieurs de la Faculté Technique du Hainaut à Mons 1944 Oct. No 8 23 pp 7 graphs & 1 map [15 refs]

Anopheles gambiae is by far the most important vector of malaria in Stanleyville and from 1935 to 1940 all efforts were concentrated on the control of this species. This paper describes the results achieved. *A. mouchelet*, *A. nili* and *A. funestus* are also vectors of malaria but their relative infrequency makes them comparatively unimportant. Thus of more than 50 000 identified anophelines captured in dwellings *A. gambiae* formed 85.5 per cent *A. nili* 8.7 *A. mouchelet* 5.6 and *A. funestus* 0.18 per cent. Of 18 396 anopheline breeding places 93.5 per cent harboured larvae of *A. gambiae*. Temporary breeding places of *A. gambiae* have necessitated close and constant supervision. oiling or filling was used in their treatment. Permanent breeding places have necessitated drainage works. Creeks and inlets from rivers have presented great difficulties: some success has been achieved by providing shade for breeding places with species of *Cassia*. *C. alata* which flourishes in damp situations.

In 1939 oiling which previously had been done at 10-day intervals was carried out weekly thereafter there was a marked diminution in the anopheline infestation of houses. But the improvement was not reflected in any diminution in the parasite rate of children between 5 and 10 years of age. This rate was 95.7 in 1940. The spleen rates of children of the same age were much lower than those reported for Stanleyville by SCHWETZ in 1931. He reported a rate of 94.8 as compared with 37 in 1940 but the fall preceded the antilarval work reported in this paper.

Of the positive blood slides from children aged 5 to 10 *P. falciparum* was found in 94.5 per cent, *P. malariae* in 22 per cent, and *P. vivax* in 4.5 per cent. *Anopheles* dissected numbered 36 826. The sporozoite index of 30 780 *A. gambiae* was 6.49 of 3 589 *A. nili* 4.3 of 2 062 *A. mouchelet* 4.4 and of 375 *A. funestus* 6.6.

REV PALUDISME ET MÊD TROP 1945 Dec. 15 v 3 No 21 167-76. La lutte contre le paludisme dans la Franco d'Outre-Mer [Malaria Control in French Overseas Territories.]

[April, 1946]

FELTON H. L. BARNES R. C. & WILSON A. *Malaria Control in a Non-endemic Area.* *J National Malaria Soc.* Tallahassee Fla. 1945 Sept. v 4 No. 3 201-8. [16 refs.]

The return of service personnel and the introduction of prisoners of war from many parts of the world, infected with malaria involves risks not limited to those parts of the United States in which malaria is endemic at the present time. This paper describes the activities of a sub-office of Malaria Control in War Areas with headquarters in New York that is responsible in collaboration with local authorities for the execution of preventive measures around military installations in the New England States New York New Jersey Pennsylvania and Delaware. Mobile malaria control units have been established at strategic places. Each unit consists of a station wagon and a 1½-ton truck which carries material for entomological surveys and inspections larvicidal operations minor drainage clearing and cleaning and spray-killing adult mosquitoes an engineer or entomologist is in charge and is accompanied by the necessary semi-skilled assistants. Surveys are made around concentrations of prisoners of war and service personnel and assistance is given to local agencies making such surveys in non-military areas. Mosquito control measures are carried out wherever human carriers and the mosquito vector are concentrated. In addition demonstrations have been given to district and local public health officials and laboratory workers have been given to district the recognition of malaria parasites in thick films.

During 1943 and 1944 57 areas were surveyed in all of these north-eastern States except Vermont. *A. quadrimaculatus* was present in 32 of these 57 areas adults were found in all the States except New Hampshire where however larvae of this species were taken. In nine localities *A. quadrimaculatus* densities were high. Maximum *A. quadrimaculatus* counts for single catching-station inspections were as high as 500 in Rhode Island 325 in Delaware 200 in Massachusetts 150 in New Jersey and 100 in New York. It would seem that high densities of *A. quadrimaculatus* may be found in all of the north-eastern States except Maine Vermont and New Hampshire.

PARAENSE L. Aspectos parasitários observados no local inoculado com esporozoítos de *Plasmodium gallinaceum* (Nota preliminar) [Parasitologia.] Mem Inst Oswaldo Cruz 1943 June v 33 No 3 353-9
1 coloured pl English summary

The paper reports the results of an investigation into the development of sporozoites of *P. gallinaceum* when injected by mosquito bite or by syringe into the skin of chicks. The skin at the site of injection was removed at varying intervals and pinned out on a board with the subcutaneous surface uppermost. Scrapings were then made of the dermis and with the material thus obtained films were made. These were stained with Giemsa stain and searched for possible developmental forms of the malarial parasite. Films made from skin 6 to 12 hours after injection showed many elongate bodies with eight or more chromatin granules. They were considered to be evolutionary forms of sporozoites. At the 18, 24, 60 and 84-hour periods the films showed small intracellular oval bodies with one or two chromatin masses. After the 84-hour period parasites appear in the blood following which after 1, 24 and 48 hours smears from the injection sites reveal numerous erythrocytic schizonts within large cells. The paper is illustrated by a coloured plate depicting some of the developmental forms encountered.

SEELER A. O. MALANGA C & PIERSON J. Effect of Streptomycin on Avian Malaria. Proc Soc Exper Biol & Med 1945 June v 59 No 2 291-2
C M Wenyon

The authors have tested the action of streptomycin on three species of avian malarial parasite (*P. cathemerium*, *P. lophurae* and *P. gallinaceum*) in Leghorn chicks. The infections were produced by intravenous inoculation of infected blood, and, in the case of *P. gallinaceum* of sporozoites also. Treatment was commenced within an hour of inoculation by intramuscular injection of the antibiotic every three hours during five days (three days in the case of the sporozoite induced infection). The birds were in groups of five and the dose for each group varied from 25 000 to 400 000 units per kilogram of body weight per day. The effect of the drug if any was estimated by parasite counts made on the fifth day (ninth day in the sporozoite-infected birds). In the blood-inoculated birds the infections developed as in the controls but in those inoculated with sporozoites the percentage of infected cells in the blood varied from 40.8 to 17.7 according as the doses of streptomycin varied as indicated above. In 10 control chicks the percentage of infected cells was 35.1. The results indicate that streptomycin has no suppressive action on the blood inoculated infections but has a slight action on those induced by sporozoite inoculation.

ROSTORFER H. H. & RIGDON R. H. Anoxia in Malaria. An Experimental Study on Ducks. J Lab & Clin Med 1945 Oct. v 30 No 10 860-66
4 figs.
C M Wenyon

In previous papers the second author has shown reason for supposing that anoxia plays an important part in deaths from *P. falciparum*. *P. knowlesi* and *P. lophurae* infections [this Bulletin 1943 v 40 118 and 436 1945 v 42 540]. Recently with VARNADAE (Amer J Trop Med to be published) he has shown that transfusion of red cells will prolong the course of the infection in ducks but will not prevent ultimate death. In the present paper an account is given of experiments in which chicks and ducks infected with *P. lophurae* were exposed to reduced oxygen tension. This was accomplished by keeping

them in a special chamber in which atmospheric pressure could be reduced to represent the conditions of altitudes up to 20 000 feet. The rate of "ascent" was 1 600 feet per minute during the first 12 minutes followed by 600 feet per minute. It was found that both normal and infected chicks and ducks succumbed to the reduced oxygen tension, but that the infected birds did so before the normal birds. The normal birds developed a polycythaemia of 4 million red cells in comparison with a normal of 2.5 million. In ducks this level was reached in three days.

In another experiment a comparison was made of four infected ducks kept at normal atmospheric pressure and four at the reduced pressure of 20 000 feet. The total red cell count showed an increase on the second day and a subsequent fall, in both groups. The fall is however more rapid in the normal-atmosphere group while the total number of parasitized cells is one-third greater in the reduced pressure group. The total number of unparasitized cells decreases rapidly in both groups so that, ultimately the complete loss of these cells seems evident. The formation of young cells is more rapid in birds kept at high altitude. The increase in number of the new cells does not prevent the rapid disappearance of the old cells. The rate of disappearance of adult cells is the same in both groups though the total parasite count is higher in the reduced-atmosphere group. Observations were also carried out on six ducks two of which were kept at normal atmospheric pressure and four at reduced pressure. Of the four two were removed from the chamber after five days. The results were very much the same as in the previous experiment. Of the two removed after five days one recovered and its rate of recovery was approximately the same as that of one of the two kept at a normal pressure which also recovered.

The experiments indicate that birds with a mild infection do not tolerate severe anoxia such as occurs at high altitudes. They first show the effects of anaemic anoxia before the infection has reached the stage at which malarial symptoms would become evident. The symptoms of anoxia in infected and uninfected birds are the same with the difference that they appear at a lower altitude and after a shorter exposure in the former group. It appears that the decrease in resistance to anoxia in infected birds is the result of the failure of the oxygen transporting system to meet reduced oxygen pressure. The high total parasite count in infected birds at high altitudes is a result of the induced polycythaemia and the greater opportunity the parasites have of infecting red cells.

The authors conclude that the data presented in their paper lend support to the view that anoxia plays an important rôle in the mechanism of death from acute malarial infections.

C. M. Wenyon.

RIGDON, R. H. & RUDISELL, H. Jr. Effect of Radiation on Malaria. An Experimental Study in the Chick and Duck. *Proc Soc Exper Biol & Med.* 1945 June v 59 No. 2, 167-70 2 figs.

One of the authors (H. R.) having shown that splenomegaly resulting from chronic malaria was reduced, with corresponding improvement in health by treatment with Roentgen irradiation it was considered of interest to investigate the effect of irradiation on more easily controlled malarial infections. Those of *P. lophrae* in chicks and ducks were selected. In the first place citrated infected blood was exposed in Petri dishes to varying amounts of irradiation, and was then inoculated intravenously to chicks and ducks. It was found that the intensity of infection produced in a given time decreased with the amount of irradiation till finally an amount was reached which rendered the blood entirely non-infective. When infected chicks were exposed to the rays there was a reduction in the intensity of the infection, the greatest reduction being in the

chicks which had been exposed to the greatest amount of irradiation. The effect of radium bromide was tested by mixing a solution of this substance with citrated infected blood in Petri dishes or by inoculating the solution intravenously to infected chicks and ducks. In neither case was there evidence of any lethal action of the drug on the parasites though in the case of the *in vivo* test the amount administered was sufficient to cause severe tissue degeneration. In the Roentgen ray experiments as the amount of irradiation needed to bring about a significant reduction of the infection was very near the dose lethal for the chicks and ducks it would seem that this type of therapy for malaria would be impracticable unless other malarial parasites proved much more susceptible. Similar experiments with *P. gallinaceum* have been described by BENNETSON and COATNEY [this *Bulletin* 1945 v 42 623] C M Wemyss

1. FREUND J SOMMER Harriet E. & WALTER Annabel W Immunization against Malaria Vaccination of Ducks with Killed Parasites Incorporated with Adjuvants. *Science* 1945 Aug 24 200-202.
- ii. — THOMSON K. J SOMMER, Harriet E WALTER Annabel W & SCHENKED Edna L. Immunization of Rhesus Monkeys against Malarial Infection (*P. knowlesi*) with Killed Parasites and Adjuvants. *Ibid* 202-4 [Refs in footnotes.]

Experiments by various observers have shown that antibody production against certain antigens is increased and made to last longer if the antigens injected are combined with a lanoline like substance (Falba) and paraffin oil with or without killed tubercle bacilli [see *Bulletin of Hygiene* 1945 v 20 585]. In the papers under review experiments are described in which this procedure was applied in attempts to immunize young ducks against *Plasmodium lophurae* and *rhesus* monkeys against *P. knowlesi* both of which usually produce fatal infections.

i. In the first paper the experiments with ducks are considered. Heavily parasitized red cells were suspended in salt solution containing 0.1 per cent formaldehyde and kept at a temperature of 4°C. overnight. The cells were then washed three times with saline and mixed with Falba and paraffin oil. The ducks to be protected received two injections of this mixture together with killed tubercle bacilli and one injection of the mixture without tubercle bacilli a period of one month intervening between the injections. A month after the last injection of antigen in each of two experiments four immunized and four control ducks received approximately one billion parasites intravenously. The blood examinations carried out clearly indicated that the intensity of infection in the immunized ducks was very much lower than in the controls. Thus in the first experiment none of the immunized ducks showed more than an average of 7.6 parasites per 100 red cells while none of the controls showed less than 54. Two of the controls died from their malaria infection. One of the immunized ducks also died the cause of death being generalized peritonitis. It is clear that the immunized ducks had acquired a considerable resistance to subsequent infection with *P. lophurae*.

ii. In the second paper are discussed similar experiments with *rhesus* monkeys and *Plasmodium knowlesi*. The antigen was prepared from heavily infected blood as described above and monkeys received two or three subcutaneous injections of this antigen with killed tubercle bacilli. When injected intravenously with infected blood 14 control monkeys rapidly became infected. Of these four died of malaria nine most if not all of which would have died, were killed in order to recover parasites for vaccine production while one survived. Of similarly treated immunized monkeys one failed to show parasites at any time in thin smears while 6 developed infections of 1 to 10 parasites per 100

red cells. These subsequently disappeared. It is concluded that the method of immunization modifies parasitaemia and prevents fatal infection with *P. knowlesi* in rhesus monkeys. C. M. Wexon

TRYPANOSOMIASIS.

CAUBET P. Différences morphologiques chez deux souches de *Trypanosoma gambiense* déterminant des maladies expérimentales différentes. [Morphological Differences between Two Strains of *Trypanosoma gambiense* causing Different Experimental Infections.] *Bull. Soc. Path. Exot.* 1944 v 37 Nos 9/10 285-90 2 figs. [15 refs.]

The author measured the trypanosomes of two laboratory strains of *Trypanosoma gambiense* using stained thin blood films and a camera lucida. One strain called the Antwerp strain produced acute infections in mice and rats, while the other called the Yaunde strain [Cameroons] caused chronic and irregular infections and sometimes produced paralysis in mice. The latter strain has been the subject of previous observations (see ROUBAUD & PROVOST this *Bulletin* 1939 v 36 746 1942 v 39 234 STÉFANOPOULO & ETÉVE *Ibid.* 1945 v 42, 258).

The measurements of the two strains are shown in tables and curves. The trypanosomes of the Antwerp strain were in general shorter than those of the Yaunde strain, owing chiefly to differences in the length of the free flagellum. In the Antwerp strain the total length of the trypanosomes varied from 18 to 30 μ (average 24.5 μ) in the guinea pig and from 16 to 28 μ (average 22.9 μ) in the rat while the corresponding figures for the Yaunde strain were 20 to 34 μ (average 29 μ) and 20 to 34 μ (average 27.8 μ).

These differences between the two strains were maintained through many passages in animals during six months and the strains could readily be distinguished in thin blood films on simple microscopic examination.

In accordance with the views of LAVIER [this *Bulletin* 1944 v 41 368] the author thinks that the morphological differences may be associated with differences in the rates of multiplication of the trypanosomes, the longest ("oldest") forms tending to be eliminated among the rapidly dividing trypanosomes of the Antwerp strain. J. F. Corson.

JACKSON C. H. N. Comparative Studies of the Habitat Requirements of Tsetse Fly Species. *J. Animal Ecology* 1945 May v 14 No. 1 46-51

In an attempt to discover why different species of *Glossina* are found in different types of country *G. morsitans* and *G. palpalis* were introduced into territory where *G. swynnertonii* normally occurs. This was done by allowing pupae brought from indigenous areas to hatch in the new habitat.

The *morsitans* were able to produce a second generation in the new environment, but were physiologically inferior to *morsitans* in a normal habitat, being smaller and containing less reserve fat. It is suggested, however, that this species would die out not so much for physiological reasons but because the predominant *swynnertonii* males would impregnate the *morsitans* females such females are either barren or produce few mostly sterile offspring.

G. palpalis did not produce a second generation under the new conditions although a seasonal stream (containing water at the time of the experiment) was in the vicinity.

Laboratory experiments to elucidate these results are described, and future work is suggested. The ability of each species to colonize a particular type of

country appears to be related more to its behaviour (frequency of feeding, choice of resting place) than to its straightforward physiological reactions to climatic conditions

Kenneth Mellanby

GASCHEN H. La répartition des tsétsés en fonction du climat. [The Distribution of Tsetse Flies in relation to Climate] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 5/6 172-5.

—— L'utilité du climogramme pour l'étude de la biologie des tsétsés. [The "Climogram" in the Study of Biology of Tsetse Flies.] *Ibid.* 176-80 1 fig

Details are given of how the limiting conditions of temperature and humidity under which *Glossina tachinoides*, *G. morsitans* and *G. palpalis* occur can be determined and expressed graphically, and the way in which these climatic conditions are related to other factors such as vegetation in the ecology of the tsetse is discussed. The ideal climatic zone for *G. tachinoides* is very much larger than that for *G. palpalis* which is much more susceptible to adverse conditions such as high temperature and low relative humidity. *G. morsitans* is intermediate between the other species in the range of its climatic requirements

K. Mellanby

GASCHEN H. Variations saisonnières des tsétsés [Seasonal Variations of Tsetse Flies.] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 7/8 250-53 2 figs

The relative abundance of *Glossina palpalis* and *G. tachinoides* at different seasons of the year is related to the changes in the temperature and humidity at the different seasons. The author considers that there is a close correlation between the abundance of *G. palpalis* and the moisture of the air from March to June when the relative humidity is rising from 40 to 80 per cent, the fly population increases greatly. Later in the year the fly catches are smaller owing to the wide dispersal of the flies from their dry weather foci. With the return of hot dry weather the flies are reduced in numbers and the extent over which the species can range is also restricted. *G. tachinoides* being much less susceptible to desiccation is less closely dependent on a favourable atmospheric humidity and variations in the density of *G. tachinoides* population are not correlated in the same way

NEEL, R. Sur un cas de trypanosomiose africaine au début, avec complications rénales observé chez un Européen au Soudan. [An Early Case of Sleeping Sickness with Renal Complications, in a European.] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 3/4 100-107 3 figs.

LWOFF M. Mme. BOVET D. & FUNKE A. Activité *in vitro* sur les trypanosomides de quelques dérivés de l'éthylène diamine. [Action of various Derivatives of Ethylenediamine on Trypanosomidae *in vitro*] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 7/8 229-36.

It had previously been shown that a number of derivatives of ethylenediamine possess therapeutic properties against *T. brucei* infections in mice (FUNKE, BOVET and MONTEZIN this *Bulletin* 1944 v 41 734). These were of the types —

where R and R are various hydrocarbon radicles. The present studies are intended to show whether such compounds exhibit any activity against artificial cultures of flagellates. The organism chosen for the tests was *Sirigomonas*

oncopelti a non-pathogenic parasite of Hemiptera and plants a peptone-saline culture medium being used adjusted to pH 7.0. One compound was tested also against *Leishmania tropica* *L. donovani* and *Trypanosoma cruzi* in a semi-solid blood-containing culture medium. The experiments were conducted at 26-28°C. in drug-concentrations of 1/1 000 1/2 000 1/5 000 and 1/10 000.

Eighteen compounds were tested results being presented in a Table. The authors' conclusions are that the degree of correspondence between the findings *in vitro* and those previously obtained *in vivo* varied in different chemical groups as follows —

(a) Monosubstituted derivatives of ethylenediamine showed a very close correspondence of activity *in vitro* and *in vivo*. For example considerable activity was shown both *in vitro* and *in vivo* where $R=C_6H_5$, i.e. N-*p*-cyclopentylbenzylethylenediamine and where $R=C_6H_5$, i.e. N-*p*-*n*-propylbenzylethylenediamine and N-*p*-isopropylbenzylethylenediamine. The latter compound was the only one tested also against *Leishmania tropica* *L. donovani* and *T. cruzi* and a degree of activity *in vitro* was demonstrated against these organisms similar to that displayed against *Strigomonas oncopelti*. Methylation of the benzene ring in the last-named compound apparently resulted in no great loss of activity *in vitro* or *in vivo* but introduction of an amino group on the ring led to considerable loss of activity under both these experimental conditions. Other compounds inactive *in vitro* and *in vivo* were the unsubstituted member ($R=H$) and that in which an amino group occupied the position of R.

(b) There was also close correspondence between results *in vitro* and *in vivo* with several compounds of types similar to those above but containing a naphthalene instead of a benzene ring. Thus N (1-naphthylmethyl)-ethylenediamine was only feebly active *in vitro* and *in vivo* but substantial activity was shown under both these conditions by N-(5,6,7,8-tetrahydro-2-naphthylmethyl)-ethylenediamine and N-(4-isopropyl-1-naphthylmethyl)-ethylenediamine as well as by the only non-aromatic diamine examined, N-citronallyl ethylenediamine.

(c) Among the remaining compounds tested there was less correspondence between results *in vitro* and *in vivo*. Thus a certain degree of activity *in vitro* but none *in vivo* was exhibited by the two symmetrical disubstituted compounds tested (see general formula II above) where $R=H$ or C_6H_5 (isopropyl). This was also the case with two compounds in which the ethylenediamine chain was replaced respectively by 1,8-diaminohexane and by piperazine.

(d) The reverse effect i.e. inactivity *in vitro* associated with substantial activity *in vivo* was exhibited by a phenylarsonic acid substituent of ethylenediamine $m-O\backslash\text{AsOH}_2$ As C_6H_5 , NH_2 , $(CH_2)_2$, NH_2 . This finding is in line with the well-known property of phenylarsonic acids in general, whereby activity comes into play only after reduction by the tissues to the arsenoxide form.

LAUNOY L. Distinction, par l'action des diamidines, entre la chimio-résistance naturelle présentée par *T. congolense* et la chimio-résistance acquise par *T. annamensis*. [A Distinction, shown by the Action of Diamidines, between the Natural Drug Resistance of *T. congolense* and an Acquired Drug Resistance of *T. annamensis*.] Bull. Soc. Path. Exot. 1945 v 38 Nos. 1/2 37-42.

The author compared the action of three aromatic diamidines—4,4-diamidino stilbene [stilbamidine M. & B 744] 4,4-diamidino diphenoxy propane [propamidine M. & B 782] and 4,4'-diamidino diphenoxypentane [pentamidine M. & B 800]—on two species of trypanosomes *T. congolense*

and a strain of *T. annamense* the latter having an acquired resistance to some compounds of antimony. The drugs were tested on these infections in mice and guineapigs.

T. congolense—In mice doses of 0.4 to 0.6 mgm. per 20 gm. body weight given intravenously caused a temporary disappearance of the trypanosomes from the peripheral blood but did not cure in guineapigs doses of 1 to 1.25 mgm. per 100 gm. body weight given intraperitoneally had little or no effect on the infection.

T. annamense—In mice 0.01 mgm. of stilbamidine caused a temporary disappearance of trypanosomes from the peripheral blood and 0.6 mgm. cured. 0.25 mgm. of propamidine cured some of the mice while 0.1 mgm. of pentamidine cured some and 0.2 mgm. cured all. In guineapigs doses of 1 to 1.25 mgm. of stilbamidine or pentamidine per 100 gm. body weight caused temporary disappearance of the trypanosomes but these doses of propamidine had no effect.

The author concludes that *T. congolense* a species with much natural resistance to drugs and this strain of *T. annamense* with an acquired resistance to some organic antimonials behaved differently towards the diamidines especially in the guineapig. [See also this *Bulletin* 1939 v 36 212.]

CHEN G. & GEILING E. M. K. The Determination of Antitrypanosome Effect of Antimonials In Vitro. *J. Infect. Dis.* 1945 Sept-Oct v 77 No 2 139-43 4 figs.

A method has been developed for the assay of trypanocidal substances *in vitro* based on the fact that they interfere with the metabolism of glucose by the parasites for which this substance is essential. The experiments were carried out with *T. equiperdum* which was maintained by passage in rats. The trypanosomes were isolated from the blood elements by centrifuging under standard conditions (the speed of centrifuging is given as 12 r.p.m. no doubt in error) and suspended in a medium consisting of equal volumes of rat plasma, M/15 phosphate buffer pH 7.4 and Ringer Locke solution containing 0.75 per cent. glucose. Drugs were dissolved in the phosphate buffer before admixture with the other components. Over a period of 1 hour at 37°C. the rate of metabolism of glucose by the trypanosomes was constant as estimated by the ceric sulphate microtitration method (MILLER & VAN SLYKE *J. Biol. Chem.* 1936 v 114 582). The rate and degree of inhibition of glucose metabolism by drugs at different concentrations over the same period was also estimated. The percentage inhibition was used to compare the trypanocidal potencies of different antimonials and comparisons were based on the concentration that would give rise to a 50 per cent inhibition. The present results obtained *in vitro* with trivalent antimonials were in good agreement with those previously

of the important centres of oriental sore kala azar has not yet been identified. kala azar in dogs has been discovered in a number of localities since the first case was seen in Jerusalem just before the recent war. During the five years of the war 13 or more foci of canine infection have been found. It is interesting that up to the present no cases of purely cutaneous leishmaniasis in dogs have been noted, though animals suffering from kala azar may develop cutaneous lesions. It is evident that further observations are required before the complete distribution of the various types of leishmaniasis in Palestine can be estimated. The centres at present known to be infected are marked on a map of the country which illustrates the paper

SENKJIE, H. A. & LEWIS, Ruth A. *In vitro* Effects of Specific Immune Blood on certain Blood and Tissue Flagellates. *Proc Soc Exper Biol & Med* 1945 June v 59 No. 2, 185-8.

The experiments described in this paper show that when immune sera are added to media in which certain flagellates are growing there is a specific action on the homologous organisms. Immune sera were prepared in rabbits by intravenous injection of cultures of three species of *Leishmania* (*L. donovani*, *L. brasiliensis*, *L. tropica*) and *Trypanosoma cruzi*. When these organisms were grown in rabbit blood agar containing 5 per cent. of immune sera it was found that the effect was very marked in the case of *T. cruzi* and *L. donovani* but much less so in the case of *L. tropica* and *L. brasiliensis*. In each case however, the action was on the homologous organism. The factors responsible were contained in the sera, for if washed red blood corpuscles were added to the medium instead of serum, there was no action. The factors are thermostable at a temperature of 56°C but they are partially destroyed at 70°C. Under the action of a homologous serum the culture flagellates first lose their motility and become agglutinated, later they round up and swell, while finally with lysis of the internal structures they die. It was shown that complement is not necessary for this action, and that the active principle is different from ablastin

DOSTROVSKY, A. The Incubation Period in Experimental Cutaneous Leishmaniasis. *Acta Med Orientalia (Palestine & Near East Med J)* 1945 Sept. v 4 No 9 303-5

The author inoculated culture forms of *Leishmania tropica* into the skin of the left upper arms of four volunteers, the doses being 16, 4, 5 and 2 million flagellates respectively. In each case there was an immediate reaction, which, in 24 hours showed as a red area with elevated centre. Without regression these lesions developed in the next few days into typical leishmania ulcers. It is held that the large doses of flagellates injected were responsible for the clinical absence of any incubation period. *Leishmania* were found in smears from three of the ulcers. The fourth was still under observation.

HAMILTON, H. L. Specificity of the Toxin Factors associated with the Epidemic and the Murine Strains of Typhus Rickettsiae. *Amer J Trop Med* 1945 Sept. v 25 No. 5 391-5

As has already been found by other workers the complement fixation titres of sera from patients suffering from epidemic typhus were observed to be far

higher against epidemic than murine antigens so also the author found that the same sera neutralized much greater amounts of epidemic than of murine rickettsial toxins. When sera from patients suffering from endemic murine typhus were subjected to similar comparative tests it was found that the complement fixation titres indicated a high degree of specificity being much higher when murine antigen was used, but with the toxin-neutralizing tests the differences in titre were considerably less in some cases the sera were capable of neutralizing only twice to four times more murine than epidemic toxin.

This incomplete degree of correlation suggested that the complement fixing antibodies might not be the same as the toxin neutralizing antibodies. The author concludes however that the toxins associated with epidemic rickettsiae are immunologically distinct from those associated with murine rickettsiae.

John W D Megaw

CHUNG H L. On the Susceptibility of *Phthirus pubis* to Infection with Typhus Virus. *Chinese Med J* Washington 1944 Oct-Dec v 62, No 4 331-3

Three batches of crab-lice were fed for seven to nine days on three typhus patients. Suspensions of the lice were inoculated into guinea-pigs which showed typical febrile reactions and not infrequently also scrotal swelling. Rickettsiae described as *R. prowazeki* were isolated from the guinea-pigs. The author suggests that in certain circumstances the crab-lice may act as a transmitter of typhus fever but he points out that the experiments do not prove that the organisms multiply in the lice which may have served merely as reservoirs of the infected blood.

BRUG S L. Op Rickettsia gelijkende vormsels in de menscheijke long [Rickettsia-like Bodies in the Human Lung] Reprinted from *Nederl Tijdschr v Geneesk* 1941 Dec. 20 v 85 No 51 4636-9 9 figs (8 coloured) on 1 pl. English summary

Description of intracellular granules found in sections as well as in smears of human lungs. The granules greatly resemble Rickettsia. In 21 lungs collected at random they could be found in every case either in the smears or in the sections or in both. Probably they are normal elements of the lungs. When one is searching for virus in human material they may be mistaken for Rickettsia.

IONESCO-MIHAIESTI C & CIUCA, M. Contribution à l'étude histopathologique de la pneumonie expérimentale chez la souris par instillation nasale de Rickettsia Prowazeki. [A Contribution to the Study of the Histopathology of Experimental Pneumonia of Mice Infected by the Nasal Route with Rickettsia prowazeki] Reprinted from *Arch Roumaines Path Expér et Microbiol* Bucharest. 1943 Jan.-Dec. v 13 Nos. 1/2 1-43 52 text figs. & 17 coloured figs. on 9 pls [15 refs.]

This monograph is profusely illustrated by 52 photomicrographs and 17 excellent coloured drawings. Full details are given of the technique employed including the use of a panchromatic stain whose composition is methylene blue 1.0 gm. toluidine blue 0.25 gm. thionine 0.25 gm. azure I 1.0 gm. McNeal's methylene violet 0.5 gm. and scarlet eosin 0.75 gm. dissolved in a mixture consisting of methyl alcohol 300 cc. glycerine 200 cc. and acetone 60 cc. Fifteen drops of the stain are added to 10 cc. distilled water. Sections are stained for one or two hours washed in distilled water dehydrated in absolute alcohol for one or two seconds then treated with a mixture of one part

oil of cloves in nine parts absolute alcohol till the sections assume a violet tint. After passing through three baths of xylol the sections are mounted in Canada balsam.

The immediate effects produced on mice by the intranasal instillation of three or four drops of suspension of heavily infected mouse lung are severe sometimes fatal, shock. When the animal recovers from this there is very soon an intense mobilization of polymorphonuclear leucocytes in the capillaries and walls of the alveoli the rickettsiae are subjected to active phagocytosis by these leucocytes in whose cytoplasm they multiply rapidly causing disintegration of the cells. Within 10 hours or so large mononuclear wandering cells begin to replace the polymorphonuclears and in turn become destroyed by the multiplication of the rickettsiae. After about 40-48 hours the fixed endothelial cells of the arteries become invaded by rickettsiae which multiply enormously in the cytoplasm often pushing the nuclei to one side and finally either rupturing the cell wall or replacing the cell by a dense mass of the organisms. These cells correspond to those described by MOORE as occurring in the peritoneum of rats and the tunica vaginalis of guinea-pigs inoculated by the intraperitoneal route with living rickettsiae.

The cell contents on being discharged into the alveoli and bronchioles fill these with a sero-sanguineous fluid rich in rickettsiae.

The epithelial cells of the air passages were never invaded by rickettsiae even when large numbers of these were brought into close contact with the cells.

BAILEY J & GIROUD P Étude histologique des lésions pulmonaires provoquées chez le lapin par l'inoculation intratrachéale expérimentale de virus du typhus épidémique [Histological Study of Pulmonary Lesions in Rabbits due to Intratracheal Inoculation of Epidemic Typhus Rickettsiae.] *Bull. Soc. Path. Exot.* 1944 v 37 Nos 11/12, 344-7 4 figs on 2 pls.

AUBIX H. Notes sur les psychoses du typhus exanthématique. [Notes on the Psychoses of Exanthematic Typhus.] *Méd. Trop. Marseille.* 1945 Jan.-Feb.-Mar v 3 No 1 54-64

The author gives numerous examples of the various psychoses encountered in typhus fever during the incubation stage the period of defervescence and early and late convalescence. Cases are described as occurring during inapparent + in which the real nature of the illness would have been overlooked if suspicion had not been aroused in such cases a diagnosis may be impossible unless laboratory tests are carried out.

The psychoses are not as is often stated, necessarily of the confusional type. There is sometimes evidence to show an inherited predisposition to psychosis but often the attack of typhus fever appears to be the sole cause, and when this is so the prognosis is naturally more hopeful.

John W D Megeay

GIROUD P & GIROUD M L Agglutination des rickettsies test de séro-protection et réaction d'hypersensibilité cutanée. [Rickettsia-Agglutination Test Serum-Protection Test and Reaction of Cutaneous Hypersensitivity] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 3/4 84-83 1 fig

Large numbers of the tests were carried out, many of them comparative.

The rickettsia agglutination test employed was a modification of the original Weigl test. Rickettsia suspensions were made from infected mouse lungs which were ground up in formalized saline and freed from large particles by decantation. Seven droplets of the suspension were placed separately on a slide and to each was added a droplet of one of seven dilutions of the serum

to be tested ranging from 1-10 to 1-640. The slide was at once placed in a Petri dish containing a little water to prevent evaporation. After 12 hours at room temperature the slide was taken out and the droplets were allowed to dry. The films were fixed in methyl alcohol washed in water and stained for half an hour with a mixture of five drops of Giemsa stain and 1.0 cc. boiling neutral distilled water. After differentiation in equal parts of absolute alcohol and xylol the film was washed and dried. The degree of agglutination is said to be sharply defined ranging from coarse dense clumps to very small clumps among scattered free organisms.

The tests of human sera were carried out immediately before each of three injections of rabbit lung vaccine given at weekly intervals and a week after the last injection. The highest titre was usually reached a week after the second dose of vaccine but the responses were very varied the titres ranging from 1-10 to 1-640 and averaging 1-80 to 1-160. The sera of patients suffering from severe attacks of typhus fever reacted at high titres such as 1-1 500 in mild, pseudo-influenzal attacks the titres usually were 1-80 to 1-160. The reaction soon became negative.

The serum protection tests were carried out by mixing the serum with varying dilutions of virulent rickettsial cultures keeping the mixtures for half an hour at 37°C and injecting them intradermally into a rabbit. As a control the same culture without serum was injected into another part of the skin of the same rabbit.

The sera of vaccinated persons showed protective reactions of progressively increasing strength after successive doses of the vaccine. After mild attacks of typhus corresponding reactions occurred after severe attacks still stronger reactions were observed, and they remained positive for many years. The intradermal hypersensitivity test is based on the local inflammatory reaction produced in typhus patients by intradermal injections of killed rickettsia cultures. This reaction gave very varying results it usually remained negative after protective vaccination with killed rickettsiae but after vaccination with living rickettsiae and after mild attacks of typhus it soon became positive. After severe attacks the reaction was slow in appearing sometimes it was delayed for months. It remained positive for years after the attack.

There was no agreement between the responses to the serum-protection and rickettsia-agglutination tests the latter gave irregular and inconsistent results but the serum protection test gave results consistent with the amount of antigen injected. The rickettsia agglutination test was regarded as indicating the presence of antibodies of infection rather than of immune anti bodies.

SUREAU B Elimination d'agglutinines antirickettsies par les urines albumineuses du lapin inoculé par voies dermique ou péritonéale [Discharge of Anti-Rickettsial Agglutinins through the Albuminous Urine in Rabbits Inoculated Subcutaneously and Intraperitoneally] *Bull. Soc. Path. Exot.* 1945 v. 38 Nos 7/8 185-7 1 fig

Rabbits were inoculated with living typhus rickettsiae when the agglutination titre of the serum had reached a height of about 1-160 an artificial nephritis was produced by a bismuth preparation injected daily for a week. When the albuminuria became pronounced agglutinins appeared in the rabbits urine reaching a titre of rather less than 1-40 and simultaneously the agglutination titre of the serum fell to less than 1-80. With the disappearance of the albuminuria the agglutinins also disappeared from the urine and the agglutination titre of the serum rose slightly remaining constant for some time at about 1-80.

GIROUD P & SUREAU B. Les variations des agglutinines de la peau inoculée et saignée chez le lapin infecté par voie dermique avec du virus typhique. [Variations in Agglutinins from Inoculated and Healthy Skin in Rabbits Injected Intradermally with Typhus Rickettsiae] *Bull. Soc Path Exot* 1944 v 37 No 9/10 264-8 1 fig

V BORMANN & PREUSS Zur Schnelldiagnose des Fleckfiebers aus dem Blutstropfen. The Rapid Diagnosis of Typhus Fever by Blood Droplets Slide Test. *Ztschr f Immunopath u Exper Therap* 1944 Nov 18 v 105 No 4 313-30 1 fig [11 refs.]

The most useful feature of this paper is that it contains a summary of the numerous rapid modifications of the Weil-Felix and other agglutination tests. The authors give details of the method adopted by themselves in carrying out one of these modified tests in which dried cultures of *Proteus O 19* prepared by a proprietary firm, are used for the suspensions. They lay special stress on the employment of drops of suspension not larger than the drops of blood under test.

Their claim that the test is more reliable than the standard test does not appear to be valid. Among 46 patients suffering from diseases other than typhus fever and tested by their method, there were 19 positive reactions as compared with four with the standard test. Although they claim that in 378 samples of blood from typhus patients there were 103 negative responses as compared with 121 with the standard test the basis of comparison seems to be unfair because no account is taken of standard reactions at titres below 1-400 all these are included among the negative responses and their number is not stated.

John W D Meager

ORTIZ MARIOTTE C. MALO-JUVERA F & PAYNE G C Control of Typhus Fever in Mexican Villages and Rural Populations through the Use of DDT *Amer J Pub Health* 1945 Nov v 35 No. 11 1191-5 1 fig

In two Mexican villages epidemics of typhus fever were promptly controlled by dusting the clothing of the great majority of the inhabitants with a powder containing 5 per cent DDT. In one village 612 of the 671 inhabitants were treated, and in another 739 out of 1 016. Each person's head was treated with a lotion whose active principle was phenyl cellosolve [see this *Bulletin* 1944 v 41 744]. In both villages the disinfection was started while the epidemic was approaching its peak and allowing for the incubation period, the abrupt cessation was what would have been expected, assuming complete efficiency of the method.

Experiments were carried out in typhus-free villages in one with a house infestation rate of 33 per cent the clothing was treated twice with a seven-day interval two weeks later the infestation rate was 1.8 per cent. six weeks later it was 1.1 per cent. three months later it had risen to 9.5 per cent. In another village a single treatment reduced the rate from 60 to 11. two months later it had risen to 26 per cent.

The effect of phenyl cellosolve on head lice was

Some of the findings are so revolutionary that confirmation.

and
C 10-2
of opini
ely to 1

In Part I the author refers to his previous description of an epidemic in Ruanda Urundi in 1939-40 in this the rickettsiae were regarded as being murine though they seldom caused an orchitic reaction and were abnormal in some other respects. The organisms were isolated from lice bed bugs fleas and ticks in some of the outbreaks the vector chiefly incriminated was the bed bug. The mammalian reservoir was the rat in which a very high percentage rate of infection was found in the affected areas. The Weil Felix reaction was of the *Proteus* O19 type but in recent outbreaks the OXA type has become increasingly frequent. Few fatalities occurred but in some severe attacks an inoculation eschar like that of boutonneuse fever was seen.

In Part II the opinion is expressed that rickettsiae are closely related to rotozoa. The fallacies connected with the usual methods of diagnosis and research are discussed including the anomalous results often obtained by animal experiments and the Weil Felix test. Strict adherence to the technique of FELIX and BRIDGES [this *Bulletin* 1944 v 41 552 & 554] is recommended. Great advantages are claimed for the staining method of LESTOQUARD briefly this consists in fixing for 5-10 minutes in a mixture of 98 parts of 94 per cent alcohol and two parts of fresh tincture of iodine washing in alcohol drying staining for one or two hours in a mixture of 1.0 cc. distilled water (pH 7.4) and three drops each of May-Grunwald and Giemsa stain differentiation by alcohol and washing in neutral distilled water. Using this method the author claims to have shown the frequent presence of rickettsiae in the urinary sediment obtained by centrifugation in the sputum the conjunctival secretion the nasal mucus and in skin scrapings obtained by the method used in the search for leprosy bacilli.

He states that rickettsiae can easily be cultivated by adding the patient's blood to normal saline great multiplication of the organisms is said to occur in the infected white cells within a period ranging from a few hours to two or three days.

The most surprising claim of all is that during the prevalence of the disease of Léopoldville rickettsiae were found in the blood of all the 50 persons examined whether they were sick or healthy. This universal occurrence of the organisms is regarded as being comparable with what happens in malaria [prevalence in areas of hyperendemicity].

Examination of the urine gave positive results only when the disease process was active. Pronounced rickettsial infection was found in the liver cells of patients who had been retrospectively diagnosed as suffering from yellow fever because of the histological changes found in the organ. *John W D Megaw*

PANG K H *Studies on Typhus Fever Epidemic occurring in a Poor House II. Etiological and Epidemiological Studies.* *Chinese Med J* Washington 1944 Oct.-Dec. v 62 No 4 334-46 [23 refs]

This epidemic occurred in a poor house where 570 persons were living in deplorable conditions in rooms infested with rats. The conditions appear to have been eminently suitable for the occurrence of both louse borne and flea borne typhus.

Among 248 children under 11 years there were 11 cases in the 11-15 age group there were 23 cases among 196 children and among the remaining 130 persons there were 4 cases.

Two girls living in one room were attacked on April 5 1940 another girl in the same room was attacked on May 26 and then cases began to occur in various rooms. After August 22 there were no further cases till April 25 1941 when three girls occupying a rebuilt and relatively rat free room were attacked and during the next two months six further cases occurred.

Numerous strains of rickettsiae were isolated by guinea-pig inoculation of these seven were from patients eight from rats and their fleas four from body lice of patients ten from body lice of healthy inmates and one from a rat mite.

Obvious orchitis appears to have occurred in only one of the many guinea-pigs used for inoculation or transfer of the strains but rickettsiae were often detected in vaginal smears. The infection is stated to have died out after a few passages in guinea-pigs.

During the period of the main epidemic only four of the 18 rats examined were infected and in the inter-epidemic period seven of 12 rats were found infected.

Inoculation experiments with batches of lice collected from healthy inmates gave the following results—one batch collected May 18 1940 was infected two batches collected June 17 and 25 1940 at the height of the epidemic, were infected only one among ten batches collected during the winter epidemic period up to January 1941 was infected between February and April 1941 "most of the batches examined were infected," and during the recrudescence of the infection all the three batches tested were infected.

All the strains isolated were regarded as murine but transmission was believed to be by lice

PANG K. H. ZIA, S. H., CHEN S. M. & FENG Y. S. Studies on Typhus Fever Epidemic occurring in a Poor House. III. Control Measures, with special reference to the Use of Typhus Vaccine. *Chinese Med. J.* Washington. 1944 Oct.-Dec. v 62, No. 4 347-50.

The author describes the results obtained by the use of a locally prepared tissue-culture vaccine in the control of an institutional epidemic.

Among 97 vaccinated girls there were five attacks (5.2 per cent.) against nine attacks (9.6 per cent.) among 105 non-vaccinated girls living in closely similar conditions. No mention is made of any difference in the severity of the attacks in the two groups the disease is stated to have been mild, and there were no deaths. Part I of this series has not been traced, the reference to it as given by the authors is incorrect.—Ed

RUGIERO H. R. & COHEN J. Nuevos casos de tifus exantemático en la Ciudad de Buenos Aires y sus alrededores. [Further Cases of Exanthematic Typhus in Buenos Aires and its Environs.] *Prensa Méd. Argentina.* 1945 Nov 9 v 32, No. 45 2203-6.

The authors have seen 11 cases of murine typhus fever in and near Buenos Aires between August 1944 and July 1945.

The cases were sporadic but six of the patients, who were attacked in January and February 1945 had been working on the same floor of a rat-infested grain store

ANDERSON W. L. & WING W. M. Tsutsugamushi Disease (Scrub Typhus) a Clinical Study of Forty Nine Cases. *War Medicine* Chicago. 1945 Sept., v 8 No. 3, 163-6

Brief clinical notes are given of 49 cases of tsutsugamushi fever which occurred in a Pacific Island among 750 soldiers who had bivouacked on a grassy plain previously occupied by Japanese troops.

The percentage incidence of the chief features was—headache 98 backache 90 chills 30 deafness 15 respiratory-system involvement 10 adenopathy

Fevers of the Typhus Group

327

90 eschar 70 rash 43 palpable spleen 40 tender lymph nodes 35
bradycardia 100 *Proteus* OXA agglutination reaction 53 leucopenia 40
minor abnormality of urine 30
In many cases there were multiple eschars. A reference is made to the
occurrence of infected bites of men from the same patrol hospitalized for other
causes. These lesions are said to have had a different distribution on the body
but they are not described.
The island had been reported to be free from infection and the authors
remark that if that is true it must be assumed that the disease had been
introduced by the Japs but he rightly suggests as a much more likely explana-
tion that the disease had existed without being recognized.

SOMERS R. B U A Case of Tick Typhus in the Sudan. [Memoranda.] *Brit*
Med J 1945 Dec 15 848 1 chart.

The special interest attaching to this case is that it is the first to be reported
from the Anglo-Egyptian Sudan. The patient was an English schoolmaster
engaged in inspecting bush schools. The fever was predominantly of a deep remittent type. It lasted about
10 days. The pulse rate was slow never exceeding 76 on one occasion when
the temperature was 103°F it was 64

A *tache noire* was present this had been seen by the patient about 10 days
before the onset no tick had been detected. There was a maculo-papular rash
with a tendency to vesication in some of the spots the rash was abundant on
the forearms and scanty on the trunk. *Proteus* OX2 was agglutinated at a
titre of 1-500; with OX19 the reaction was negative.

BOW M R. & BROWN J H. Tick-borne Diseases of Man in Alberta
Canadian Med Ass J 1945 Nov v 53 No 5 459-65 1 map [48
refs]

The authors give short notes on the history, epidemiology and clinical
aspects of Rocky Mountain spotted fever tick paralysis and tularemia with

Tropical Diseases Bulletin

special reference to their occurrence since 1933 in the Province of Alberta Canada. Six known cases and one suspected case of Rocky Mountain spotted fever have been reported in Alberta there have been two cases of tick paralysis and two cases of tick transmitted tularemia in man. In the authors opinion the tick borne diseases of man are important in Alberta they appear at present to be confined to the southern part of the Province but there are indications that further survey work might disclose a similar situation in the foothills and mountain area.

The following ticks capable of transmitting tularemia have been collected in Alberta — *Dermacentor andersoni* *Harmaphysalis leporispalustris* (rabbit tick) and *Harmaphysalis rickettsi* (bird tick) *D. andersoni* infected with *Dermacentronus rickettsi* [*Rickettsia rickettsi*] and with *Pasteurella tularensis* has been collected in the southern area of the Province.

[PARKER et al. (Public Health Reports Washington 1932, v 47 479) found strong presumptive evidence that *H. cinabarina* transmitted tularemia in sage hens but no proof that it had been implicated in human disease.]

PARRON G La fièvre des tranchées existe-t-elle en Algérie? [Does Trench Fever occur in Algeria?] Arch. Inst. Pasteur d'Algérie 1945 Sept. v 23 No. 3 180-82 1 chart

The author describes a case of fever which conformed in all its clinical features to one of the types of trench fever. There were three spells of fever each lasting about three days the spells started on the 1st, 7th and 14th days. The fever curve was of the undulant type and the total duration was 14 days. Severe nocturnal pains of the shin-bone type occurred and convalescence was slow. Repeated blood examinations including culture tests gave negative results and the author was satisfied that relapsing fever undulant fever malaria and typhoid-group fevers could be excluded. He suggests that some of the numerous cases diagnosed in Algeria as relapsing fever without spirochaetes may be examples of trench fever.

YELLOW FEVER

BATES M & ROCA-GARCIA M. The Douroucouli (Aotus) in Laboratory Cycles of Yellow Fever Amer J Trop Med 1945 Sept. v 25 No. 5 383-9 2 figs.

"Four douroucouli (*Aotus trivirgatus*) from the Villavicencio area of eastern Colombia were tested in laboratory cycles of yellow fever with the mosquito *Haemagogus capricornis* and a local strain of virus. All four animals showed acute fatal infections characterized by fever and a very high titer of circulating virus death occurred on the fourth or fifth day after infection. Three of the animals showed stomach hemorrhage and liver tissue from all four showed lesions characteristic of fatal yellow fever in man and rhesus monkeys. Virus was transmitted by the bite of the mosquito *Haemagogus capricornis* from squirrel to douroucouli douroucouli to douroucouli and douroucouli to samuri. There is some evidence that the douroucouli may be important in the epidemiology of yellow fever since it is said to be the only monkey in certain areas in Colombia where the disease is endemic.

ERRERO A. *L. Aedes aegypti*. Le danger qu'il représente pour l'agglomération Algéroise [*Aedes aegypti* Its Danger to Algeria.] [Thésis.] 100 pp 1 folding map & 4 figs. [Bibliography.] 1939 Algiers La Typo-Litho et Jules Carbonel réunies.

FAIVREL R. Immunisation du cobaye contre le virus de la fièvre jaune par scarifications cutanées [The Immunization of the Guinea-pig against Yellow Fever Virus by Cutaneous Scarification.] *Bull Soc Path Exot* 1945 v 38 Nos 3/4 77-86

The author inoculated 11 guinea-pigs with neurotropic yellow fever virus the French strain at its 218th passage in mice and 6 guinea-pigs with culture virus 17D reinforced by 10 mouse brain passages and growth again on chick embryo. In both series the cutaneous scarification method was used.

Out of the 11 animals vaccinated in this manner with the neurotropic virus 7 were completely resistant to an intracerebral inoculation of several thousand lethal doses 35 to 47 days after being immunized. On the contrary all 6 guinea-pigs vaccinated in the same way with the culture virus succumbed to yellow fever encephalitis when inoculated intracerebrally with virus 25 to 50 days after the scarification. Out of 5 guinea-pigs scarified with neurotropic virus which all gave negative mouse protection tests two were resistant when inoculated intracerebrally with the virus showing that an animal may be immune without the blood containing immune bodies in sufficient quantity to give a positive test.

The divergent results obtained with these two strains may be explained as due to the difference in neurotropism. One could also suppose that one strain had a greater affinity for the skin of the guinea-pig.

In the discussion Dr STEFANOPOULO in whose laboratory the work was performed emphasized that in the case of bacterial infections it is necessary to use a larger dose of an attenuated strain than of a virulent strain in order to produce infection. Normally the guinea-pig is not very susceptible to yellow fever virus and with culture virus it is probably necessary to use larger doses to produce immunity. He also mentioned that vaccination of human beings with culture virus by the scarification method is often insufficient to ensure protection but that subcutaneous inoculation of the same virus is efficacious.

DENGUE AND SANDFLY FEVER.

FAIRCHILD L. M. Dengue-like Fever on the Isthmus of Panama. *Amer J Trop Med* 1945 Sept. v 25 No 5 397-401 3 figs

The author studied 32 cases of a short fever seen in the Panama-Canal Zone between September 1941 and March 1942.

Among 21 cases in which the fever curve was available 13 were of the two-phase saddle back type and 7 of a continuous spiking type. The total duration of the fever in both types was about five days.

A blotchy macular rash was seen in every case. One or more groups of lymph nodes were enlarged in five cases. The leucocyte count ranged from 2 000 to 8 000 per cmm. The lymphocytes were more than 40 per cent of the total white cells in the 16 cases in which there was leucopenia.

The author discusses at some length the features in which the symptomatology differed from that described by certain authors as being characteristic of

dengue but in view of the well-known variability of that disease and of the known occurrence of outbreaks in the region there seems to be no good reason for hesitating to place the fever in the dengue group. *John W D Megaw*

CULLINAN E. R. Immunity to Sandfly Fever [Memoranda.] *Brit Med J* 1946 Jan. 5 12.

An outbreak of sandfly fever occurred in a hospital in the Middle East in the summer of 1942 (see CULLINAN & WHITTAKER, this *Bulletin* 1944 v 41 128) and in the summer of 1943 another outbreak occurred in the same hospital. In the first outbreak several persons had more than one attack, which suggested that an attack conferred no early immunity.

In the second outbreak in 1943 55 out of 142 (about 39 per cent.) of persons who were not present during the 1942 outbreak were attacked while only 13 out of 98 persons (about 13 per cent.) who were present in 1942 were attacked. The author thinks that this evidence suggests that while an attack of sandfly fever does not confer an early immunity or at most a very short-lived one it may confer a more distant immunity. [See also LEVSHITZ this *Bulletin* 1944 v 41 506.] *J F Corson*

PLAGUE.

DEVIGNAT R. SCHORTTER M. & GILLES SERVIL Mme. S. Quelques considérations sur la peste du cobaye. [Notes on Plague in the Guinea-pig.] *Rec. Travaux Sci Méd Congo Belge* 1945 July No. 4 25-36 3 diagrams.

A periodic extraction of data from routine records is a useful and serviceable exercise especially when assisted by personal memory. In the campaign against plague on Lake Albert in the Belgian Congo the Laboratory at Binkwa has played a notable part. Since 1898 more than 12 000 guinea-pigs have been inoculated in various ways with plague material, and more than 800 of these dead of plague, have been subjected to autopsy. The different modes of inoculation are classified as subcutaneous conjunctival on scarified skin and other ways. The discussion in the text accompanied by graphs and detailed tables relates to —A Standard infecting dose B Inoculation by different methods and C Data of preventive vaccination and serum prevention. This discussion is summarized —(1) Autopsies showed three different types (a) the violent septicaemia with hypertrophy of liver and spleen (b) the moderate form in which liver and spleen are enlarged and mottled and (c) that of partial resistance, where liver and spleen seem pseudotuberculous while the lung is consolidated (hepatization) and covered with whitish tubercles. (2) The duration of life is shown as a graph of the number of guinea-pigs dead on each successive day after a virulent inoculation. With a strain of maximal virulence "say the authors and 'inoculation of 10 lethal doses (54 to 155 organisms) we obtain a curve which we put forward as a unit of virulence for the determination of the severity of routine inoculations and ultimately of protection by vaccine or serum. The authors consider that this graphic method is more expressive than the simple presentation of the crude figure giving the percentage of animals dead and surviving. *W F Harvey*

COLE L. C. The Effect of Temperature on the Sex Ratio of *Xenopsylla cheopis* recovered from Live Rats *Pub Health Rep Wash* 1945 Nov 9 v 60 No 45 1337-42. [14 refs]

The danger of plague in an area is often considered to be proportional to the flea population particularly of *Xenopsylla cheopis*. The flea population is usually estimated by flea counts from trapped rats but these counts do not always give an accurate estimate of the total natural population. This paper attempts to relate the results of flea counts to the total flea population and to show how temperature changes in the environment may affect the results. Male and female fleas apparently exist in approximately equal numbers but whereas at low temperatures (below 70 F) females usually predominate in captures from rats at high temperatures (over 75°F) males are caught in greater numbers. This rise in the proportion of males captured at higher temperatures is due to an increase in the number of males found on the rats rather than to a fall in the number of females. It is suggested that the flea index should perhaps be computed for female fleas only.

Kenneth Mellanby

KALMBACH E. R. "Ten-Eighty", a War-Produced Rodenticide *Science* 1945 Aug 31 232-3

The substance referred to is sodium fluoroacetate. Its toxicity to small mammals was found during the course of the long-established search for new rodenticides carried out by the Wildlife Research Laboratory in Denver. Compound 1080 as it is known is extremely toxic to many small mammals and also to domestic animals such as cats and dogs and is a possible danger to man especially to operators who may use it carelessly. The following table gives the LD50 values —

	Mg/kg
Leghorn hens	10.00
Deer mice (<i>Peromyscus</i>)	5.0
Wood rat (<i>Neotoma</i>)	5.0
Wild Norway rats (<i>R. norvegicus</i>)	5.0
Tame white rats	2.5
Black tailed prairie dogs (<i>C. ludovicianus</i>)	2.5
Meadow mice (<i>Microtus</i>)	0.5
Domestic dogs	0.35
Fisher's ground squirrel (<i>C. beecheyi fisheri</i>)	0.35
Wild black rats (<i>R. rattus</i> subsp.)	0.1

Compound 1080 is very soluble in water and the results in rat control of exposing a solution have seldom, if ever been matched by other control methods. Similar results have been recorded when the material has been used on grain baits against field rodents.

Charles Wilcocks

RICHTER C. P. The Development and Use of Alpha-Naphthyl Thiourea (Antu) as a Rat Poison. *J Amer Med Ass* 1945 Dec 1 v 129 No 14 927-31 [Refs in footnotes]

This paper contains the first detailed announcement of the development of a new rodent poison by a team of the Johns Hopkins University working under a contract with the Office of Scientific Research and Development. Alpha naphthyl thiourea is a fine grey powder highly insoluble in water or acid solutions slightly more soluble in alkalis stable under normal conditions and with a melting point of 184°C. It is said to have the following LD50 though the details of toxicity tests on which such figures are based are not given.

Rattus norvegicus 7 mgm. per kilo *Rattus rattus* squirrels and guinea pigs 100-400 mgm. per kilo mice and dogs less than 100 mgm. per kilo Monkeys rabbits and chickens were more resistant and "5 Gm. per kilogram was required to kill 100 per cent. of groups of chickens and monkeys. In an extensive campaign in Baltimore it has been used in a mixture (2 to 5 per cent.) with finely ground grain such as maize or wheat and as a dust either on vegetable foods or blown in runways or on the surface of water. These tests have been in most areas 90 per cent. effective though no detail is given as to how such estimates were arrived at. In Norway rats and dogs death is due to drowning from pulmonary oedema a very large lymph flow through the capillaries of the lungs being produced. No antidote is known though the low solubility of the compound makes stomach lavage a useful countermeasure in cases of accidental poisoning.

R. B. Freeman.

CHOLERA

FELSENFELD O & YOUNG Viola M Simultaneous Vaccination against Bacillary Dysentery and Cholera with Toxoid Vaccine *Amer J Trop. Med* 1945 Sept v 25 No 5 421

Experiments were made to produce a reliable combined vaccine against cholera and bacillary dysentery. *Vibrio cholerae* (Inaba Ogawa and El Tor strains) *Shigella dysenteriae* and *Sh. paradyenteriae* Y were used.

Sh. dysenteriae—Several methods of preparation were tried and it was found by mouse protection tests that the strongest immunity was produced by a combination of alcohol-killed organisms and formalized culture filtrate.

Sh. paradyenteriae Y—The same procedures were used except that culture filtrate was not tried the most effective vaccine was prepared from alcohol-treated organisms.

V. cholerae—The best results were obtained with formal killed or heat killed Inaba organisms combined with formalized filtrate of Inaba or El Tor strains (the El Tor strain being finally selected)

All vaccines retained their immunizing power much longer when desiccated in a vacuum.

Tests on volunteers showed that formalized organisms combined with formalized filtrate gave rise to the strongest and most lasting antibody production. A mixture of antidyentery and anticholera vaccines did not cause more severe reactions than either alone and produced a satisfactory increase of antibody formation which persisted for a considerable length of time.

The findings indicate that continuation of these experiments is fully warranted.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS.

TSUCHIYA H. Survival Time of Trophozoites of *Endamoeba histolytica* and its Practical Significance in Diagnosis. *Amer J Trop Med* 1945 May v 25 No. 3 277-9

The author has studied *E. histolytica* as it occurs in stools kept at room temperature (22°-25°C.) incubator temperature (37°C.) and refrigerator temperature (5°C.) At room temperature the survival time of six different strains

was 6 to 16 hours. In the refrigerator it was 48 to 96 hours while in the incubator it was only 3 to 5 hours. It is evident that for diagnosis the best procedure is to examine the fresh specimen but if this must be kept before examination it may be left at room temperature for a few hours. If a longer delay is contemplated then the refrigerator is the best. In no case should the specimen be left in the incubator. Amoebae which were quite motionless after exposure to cold often resumed their activities when examined in the warm chamber. In some cases amoebae which were unidentifiable in the kept stool regained their specific characters when cultivated in suitable media. A strain of trichomonas was found to survive for 21 days at 5°C and for 15 days at 22°C. When the stool was exposed to 37°C the organism multiplied profusely for a few hours and then disappeared.

TAN C C & LI 1. *Amoebic Colitis with special reference to Perforation. A Study of 20 Autopsied Cases. Chinese Med J* Washington 1944 Oct.-Dec v 62 No 4 366-76 6 figs

Autopsy was done on twenty cases of amoebic colitis in all of which there had been clinical evidence of the condition during life. The ages of the 349 patients from whom these were obtained ranged from 3 to 62 years the majority being in their fourth decade. In half the cases coming to autopsy there was diffuse amoebic involvement of the colonic tract. Involvement of the sigmoid was seen in 17 of the 20 (85 per cent) of the caecum in 16 (80 per cent) of the rectum, ascending and descending colon each in 15 (75 per cent) and of the transverse colon in 12 cases (60 per cent). The terminal ileum was involved in 7 (35 per cent) and liver abscesses were found in 6 of the 20 cases all being in the right lobe of the liver. In 11 of the 20 cases the fatal attack of amoebic dysentery was the first attack and in 6 of these clinically primary cases there was perforation of the gut. In 3 other cases of perforation there was a history of amoebic dysentery before the fatal attack. A diagnosis of perforation was made *ante mortem* in 8 of the 9 cases where its occurrence was established *post mortem* and 8 of the 9 had received emetine either just before or after the perforation occurred. The ninth patient was moribund on admission and died in a few hours. Only one of the authors diagnosed cases of amoebiasis with intestinal perforation recovered and here spontaneous discharge of a localized abscess took place through the abdominal wall. In 5 of the total 10 (including the patient who recovered) the perforation occurred in the caecum in 4 in the descending colon in 2 in the sigmoid and in one in the transverse colon. Multiple perforation was found in 2 cases. The authors regard this complication as almost invariably fatal its diagnosis is difficult and its treatment with emetine ineffective. A R D Adams

COTTRELL J D & PEDDIE J J G. *The Diagnosis and Treatment of Chronic Amoebiasis. New Zealand Med J* 1945 Oct v 44 No 243 230-41

This paper has been written to acquaint the medical practitioner with the problems of amoebiasis in the returned soldier. It gives a good account of the condition but contains nothing original other than such statements as 'no soldier with recurrent or chronic diarrhoea should ever be dismissed as incurable until he has had the benefit of at least one full course of anti-amoebic treatment—in spite of repeated negative stool examinations and speaking of emetine. In emergency one or two doses may be given intravenously and again of quinine/cinemata. Even a 10% solution may be used in refractory cases. A R D Adams

HOWELL, G. Two Cases of Amoebic Granuloma. *Brit. Med. J.* 1946 Feb. 2, 181-2.

BRUCKMANN, G. & WERTHEIMER, E. A Study in the Toxicology of Emetine. *Acta Med. Orientalis (Palestine & Near East Med. J.)* 1945 Sept., v 4 No. 9 291-4.

It has been repeatedly said that the therapeutic effect of emetine would probably be much greater if the tolerated and toxic doses were more widely separated. It was for long known to be a "general irritant and protoplasmic poison" and more recently damage to the heart and the cornea has been described. The authors have taken in hand a more intensive study of the drug toxicologically as regards its impairment of liver function and its influence on carbohydrate metabolism, the part played by the liver in detoxification of emetine and the influence of diet on the toxicity of the drug.

Male white rats were the animals used. The description of the results is confusedly written. Thus the authors state "a single high dose of emetine was given and the animals were killed from 2 to 17 hours later" and they continue directly as follows "The higher dose 2.0 mgm. per 100 gm. rat was always fatal in 5 days" smaller doses 0.6-1.3 mgm. resulted in symptoms of emetine poisoning, but were not fatal. The higher doses caused a marked fall in liver glycogen smaller doses less. Because the body temperature fell sharply this was considered to be due not to any specific action of the drug, but to shock. To distinguish the specific influence of the drug in small doses on carbohydrate metabolism, animals were injected with doses of 0.3 mgm. and one such and one of a control group were sacrificed for glycogen determination. Under these conditions the temperature remained unchanged for 10 days but food was refused and weight began to fall after the 6th day. By feeding the controls on the same amount of food as the experimental animals had taken the previous day starvation glycogen values could be eliminated. There were no indications that repeated small doses of emetine impaired the liver function seriously.

To test the action of the liver in the detoxification of emetine the mortality among rats in which two-thirds of the liver had been removed and that among others not so treated, the animals being injected with the drug, was observed. Mortality was found to be higher among the hepatectomized rats except in those which lived for more than seven days by which time it is said, the liver tissue had been regenerated. The authors rightly point out that the fact of an organ being concerned in the detoxification of a poison does not necessarily mean that the organ is damaged by the poison.

Lastly to test the influence of diet on the toxicity of emetine the drug was given to rats on six different diets, the essential principles of which are detailed in the paper. It was found that adding protein to a balanced diet did not prolong the life of the rats although a reduction of protein lowered the animal's resistance to emetine. This reduction of resistance is ascribed to the probable impairment of hepatic function.

H. Harold Scott.

LIEBERMAN, H. R. *Isospora hominis* causing Acute Gastro-Enteritis in Man. *South African Med. J.* 1945 Sept. 22, v 19 No. 18 341-2 4 figs.

The patient described was a middle-aged European who had been living in a military camp in Durban for six months. A severe attack of gastro-enteritis with vomiting and diarrhoea developed one evening. This lasted for 72 hours. Bacteriological examination threw no light on the condition, which was not experienced by any other person in the same mess. Microscopical examination revealed *Escherichia coli*, trichomonads, Charcot Leyden crystals and red blood corpuscles as well as numerous oöcysts of *Isospora hominis*. The last named

persisted for more than 14 days by which time all symptoms had disappeared. After the patient had returned from two weeks sick leave they could no longer be found. It is concluded that the coccidian was the cause of the patient's illness.

RELAPSING FEVER AND OTHER SPIROCHAETOSSES.

LOFGREN Ruth & SOULE M H The Effect of Low Temperature on the Spirochetes of Relapsing Fever I. The Viability of Four Strains of Spirochetes stored at -48°C . II. The Structure and Motility of *Spirochaeta novyi* J Bacteriology 1945 Sept v 50 No 3 305-11 313-21 3 figs

The four strains used in this work *Spirochaeta duttoni* *S. kochi* *S. novyi* *S. obermeieri* had been maintained in rats for some 40 years. During the course of infection spirochaetes appear in the blood 24 hours after inoculation increase rapidly up to the 4th day and then suddenly decrease.

In the experiments blood was taken from the heart defibrinated by whipping and centrifuged. The layer of spirochaetes above the red cells was mixed with the serum and distributed in 0.2 ml. amounts in Cellophane tubes. After freezing in an alcohol-carbon dioxide mixture the tubes were stored for various lengths of time at -48°C . The organisms were then tested for infectivity by sub-inoculation into rats.

Spirochaete suspensions obtained on the 2nd day of disease remained infective for at least 27 months whereas spirochaetes taken on the 3rd day or later became non infective after a few days.

In a later experiment it was found that 3rd day spirochaetes were still infective after two years provided the original material consisted almost entirely of spirochaetes. The authors consider that this increased viability depends on the number of organisms in the original specimen.

A study was made of the morphology of normal forms of *Spirochaeta novyi* as compared with spirochaetes stored for seven days at -48°C . and spirochaetes which had been repeatedly frozen and thawed [the detailed descriptions cannot be summarized]. Observations on the effect of variations of temperature on motility were carried out with the help of a warming and cooling stage. The temperature of a suspension of *S. novyi* was raised to 37°C . gradually lowered to freezing point and the cycle repeated until the organisms died. The degree of motility was noted at temperature differences of 5°C . It was found that motility diminished as the temperature fell was abolished at zero and was regained, but to a lessened degree as thawing occurred. After three freezings and thawings practically all the spirochaetes were dead.

J C Broom

WOLMAN B & WOLMAN M Studies of the Biological Properties of *Spirochaeta recurrentis* in the Ethiopian High Plateau. Ann Trop Med & Parasit 1945 Oct. 10 v 39 No 2 82-93 [27 refs.]

A description of studies on the properties of an Abyssinian strain of the spirochaete of louse-borne relapsing fever carried out at Addis Ababa, Ethiopia.

The spirochaetes were cultivated in a medium composed as follows. One cc. of egg albumin was coagulated in a sloping test tube by heating to 80°C . To this was added about 10 cc. of a mixture of sterile human ascitic fluid 1 part, buffer solution (of pH 7.8) 2 parts and saline 2 parts. The addition of 1 per

cent. glucose improved the medium. The whole was covered with 1 cc. of liquid paraffin. The prepared culture medium was heated to 56°C. for one hour on three successive days.

Spirochaetes in this culture medium were found to be able to live and multiply over a wide range of temperatures. When the cultures were kept at 0°-12°C., they remained positive after eight months of daily examination, and even at 42°-45°C. the spirochaetes remained active though at higher temperatures they soon lost their virulence. They lived in cultures without passage up to a year but lost their pathogenicity at an early stage.

Spirochaetes from the severe cases lived longer in cultures than those from mild cases and first attack spirochaetes longer than those of a second attack. The solid and fluid parts of the medium also seemed to be of different importance and the solid part was found to harbour an invisible phase of the spirochaete. During the interval between two attacks all attempts to culture the organism from the patient's blood and bone marrow, liver, spleen and cerebrospinal fluid, were uniformly negative.

The cultures were found to exhibit a periodicity phenomenon, the spirochaetes disappearing and reappearing in the culture-tubes. The negative period ranged from 1 to 18 days the average being about 4 days. Simultaneous cultures usually relapsed at the same time or within a day or two of each other. There is a suggestion that the alternating immunological types also develop in cultures and that this property is independent of the antibodies of the host.

Rabbits and guinea-pigs were found to be naturally resistant to infection with this strain of *S. recurrens* but could be made relatively susceptible by blocking the reticulo-endothelial system by the injection of a suspension of carbon. Both mice and monkeys were susceptible but if the infective dose fell below about 0.5 cc. of the patient's blood, infection did not take place. The spirochaetes moreover were found to be less virulent towards the end of an attack.

The Addis Ababa strain was compared with a Debra Marcos strain which differed in the severity and mortality rate of the disease it provoked. The strains behaved rather differently in experimental animals yet the two are considered to be immunologically identical.

Lice were fed on relapsing fever patients and then kept at 37°C. and fed twice daily on the authors. Spirochaetes were continually present in the lice up to 18 days after being infected. A negative phase was not found. Neither the eggs nor the offspring of infected parents ever showed any signs of spirochaetes. Both the authors remained free from infection, thus confirming the well-known fact that the disease cannot be transmitted by the bite only of infected lice.

Relapsing fever spirochaetes were found to lose their infectivity to mice after an exposure of only 20 seconds to the ultraviolet rays of a Hanan quartz lamp at 32 cm. distance but remained motile up to an exposure of 10 minutes.

PIROT R. & BOURGAIN M. L'infection latente résiduelle cérébrale chez le cobaye au cours des récurrentes à *Spirochaeta perniciosa*: la survie du spirochète dans l'encéphale est fonction de facteurs individuels. [The Latent Residual Brain Infection in Guinea-pigs Infected with *Spirochaeta perniciosa*: the Survival of Spirochaetes in the Brain is a Result of Individual Factors.] *Bull Soc Path. Exot.* 1945 v 38 Nos. 1/2, 12-14

The authors have infected guinea-pigs with a Peruvian strain of relapsing fever (*S. perniciosa*) by the bites of *Ornithodoros* and also by direct inoculation from one animal to another. Subsequently after varying intervals, the brains of guinea-pigs that had been infected were examined for residual infection by

inoculation into normal guineapigs. The results show that in some individuals spirochaetes may persist in the brain for at least 222 days whilst in others they disappear within 45 days. Moreover brain passage through a number of animals has no effect on the virulence of the spirochaete in guineapigs. The authors are of the opinion that in the case of *S. persica* the localization of spirochaetes in the brain is an unpredictable phenomenon which seems to depend on the individual susceptibility of the host.

PIROT R & BOURGAIN M. Perte du pouvoir infectant d *Ornithodoros tholozani* infecté congénitalement par *Spirochaeta persica* et surinfecté au stade nymphal. [The Loss of the Infective Power of *Ornithodoros tholozani* Congenitally Infected with *Spirochaeta persica* and Superinfected in the Nymphal Stage.] *Bull Soc Path Exot* 1945 v 38 Nos 3/4 88-90

The authors have maintained in the laboratory a strain of *Ornithodoros tholozani* supposed to be infected with *Spirochaeta persica*. Sixty first-stage nymphs which had hatched from eggs laid by infected parents and which proved infective were allowed to engorge on a guineapig whose blood was swarming with *S. persica*. About 3 years later the 26 ticks now adult which had survived failed to produce infection when fed on guineapigs and a few months later the 18 survivors also gave negative results when fed on another guineapig.

The results suggest that even in the same batch of young *Ornithodoros* all do not show the same susceptibility to infection with relapsing fever spirochaetes and also that infected ticks seem to die out more rapidly than those which remain free from infection. (See also E. HINDLE *Parasitology* 1911 v 4 133)

PIROT R. & BOURGAIN M. Résultats de la splénectomie chez le cobaye au cours de la récurrente a *Spirochaeta persica*. [The Results of Splenectomy in the Guinea-pig on the Course of Infection with *Spirochaeta persica*] *Bull Soc Path Exot* 1945 v 38 Nos 3/4 90-93

The authors removed the spleen from five guineapigs 55 to 149 days after inoculation with *S. persica* when the blood had been negative for spirochaetes for considerable periods. In no case did spirochaetes reappear in the circulation.

A sixth guineapig splenectomized whilst a few spirochaetes were still present in the blood became negative after 7 days without showing any multiplication of the organisms. Three of the splenectomized guineapigs were reinoculated subcutaneously with *S. persica* but did not become infected while three controls showed a heavy infection. It would appear therefore that in the guineapig removal of the spleen has no effect on the immunity following infection with *S. persica*.

CATTAN R. CORCOS A & COHEN H. La forme méningée de la fièvre récurrente. [The Meningitic Form of Relapsing Fever] *Bull et Mém Soc Méd Hôpôt de Paris* 1945 Nos 21 22 and 23 304-6

The authors have observed numerous cases of louse-borne relapsing fever at the Liberation Hospital Tunis. They also mention the existence of a widespread epidemic of this disease throughout Tunisia which broke out early in 1944 and had not ended at the time of their communication (June 29 1945). Clinical details are given of four cases showing simple meningitic forms of

[April, 1948]

the disease all of which readily responded to treatment with novarsenobenzol. In addition two cases are added in which it was not quite possible to dissociate the symptoms from those of a chronic intoxication.

The authors suggest an analogy between relapsing fever and leptospirosis in both of which the liver may be affected, or meningitic symptoms develop and in both of which relapses usually occur. In view of the importance of the meninges in the development of syphilis meningotrophism would seem to be one of the more characteristic features of human spirochaetal infections.

WOLMAN M OMAR M & ABUL TALEB M. Louse-borne Relapsing Fever treated with Calcium Gold Keratinate. *Lancet*. 1945 Dec. 15 773-7 1 chart.

An account of the treatment of Egyptian patients infected with louse-borne relapsing fever carried out at the Imbaba Fever Hospital, Cairo. The mortality of this epidemic averaged 2.6 per cent. but many of the patients had intercurrent diseases. A series of 100 patients whose blood contained spirochaetes and who also had pyrexia, were divided into two groups of 50 each. Patients in one group were given intravenous injections of 0.5 gm. neosalvarsan in 5 cc distilled water and those in the other group were left untreated. The drug caused frequent but mild reactions and no significant difference was found between those given 0.5 gm. neosalvarsan in water and a small group of patients not included in the above experiment, who were given 1.0 gm. neosalvarsan dissolved in water or calcium thiosulphate.

The injection of the drug caused the disappearance of spirochaetes within 24 hours in all cases and in most the temperature also came down within the same period and invariably within 30 hours.

In the treated group 17.5 per cent. had relapses and 5 per cent. non-specific rises in temperature the corresponding figures in the control group being 65.0 and 11.2 per cent. Moreover the mean length of interval between the attacks was significantly longer in the treated group. Three patients in the experimental group and one in the untreated group died of the infection.

HUTCHISON J H PIPPARD J S & GLEESON WHITE, M H. SHEEHAN H. L. Outbreak of Weil's Disease in the British Army in Italy. Part I. Clinical Study (HUTCHISON PIPPARD & GLEESON WHITE, *Brit Med J* 1946, Jan. 19 81-3. Part II. Post Mortem and Histological Findings (SHEEHAN) *Ibid* 83.

The description of an outbreak of Weil's disease among British soldiers in Italy who had all bathed in the River Arno or its tributaries, and in bomb craters during August and September 1944. There were 17 undoubted cases, 5 fatal, all of which ran a similar course. The onset was sudden, with general weakness, shivering and high fever, nausea and sometimes vomiting. Severe headache was common though sometimes delayed, and general stiffness and aching developed during the next few days. The severe pain decreased when jaundice developed.

Intense conjunctival suffusion was constant and early in appearing. Icterus developed between the third and eighth days of illness and with one exception had a remarkable orange-yellow tint. The icterus persisted for weeks. Haemorrhages varying in degree were seen in every case. Visceral bleeding was common and was a factor in the death of the five fatal cases. A striking feature common to all cases was some degree of oliguria which in three of the fatal cases and two others became anuria for variable periods.

Treatment with penicillin 15 000 units 3-hourly up to a total of 600 000 to 660 000 units was tried in six cases. One patient died after receiving 210 000 units and there was no obvious effect on the course of the disease in the other five. Anti leptospiral serum was used in three cases also without any obvious beneficial effect.

Guinea-pigs were inoculated with blood (5 cc.) taken from 15 cases on the 3rd to 11th days of illness and two with 10 cc. of urine from two other cases on the 13th and 16th days respectively. Five of the animals died with typical symptoms of infection with Weil's disease and leptospires were grown from the kidneys of three of them. The blood of 13 of the patients was examined for agglutinins against local Cartwright strains or stock Wijnberg strains and all gave positive tests at a diagnostic level of 1/300.

Convalescence was slow in each of the 12 patients who recovered and they were not fit for discharge to a convalescent depot until 17 to 20 weeks from the onset of the disease. All except one showed anaemia which responded very slowly to iron therapy.

During the period when these men were in the wards over 1 800 cases of infective hepatitis were seen but only rarely did this disease simulate Weil's disease and the possibility of confusion between the two is remote. There were two doubtful cases thought to be enteric fever with jaundice until after recovery their blood was found to contain a rising titre of anti leptospiral agglutinins. Non-icteric leptospirosis may also have been present among some of the milder cases of P.U.O.

After the first cases were diagnosed an embargo was placed on unauthorized bathing etc. and the epidemic came to an end. At least two out of every ten rats caught in the neighbourhood were found to be carriers.

The post mortem and histological findings on six cases from this epidemic including the five referred to above are also described. The most characteristic features were prominent lesions in the kidneys involving cast obstruction and epithelial damage in the collecting tubules and also in the second convoluted tubules and the monocytic infiltration of the intermediate zone. There is said to be a close similarity between the appearances of the kidney in Weil's disease and in patients who died as a result of haemolytic transfusion reactions.

In every case brought to autopsy there was deep icterus of the skin and other tissues but the liver showed no obvious abnormality and microscopically there was never any trace of recent or healing necrosis nor of degeneration of the hepatic cells.

CURRENTS J. H. & WOODARD R. C. *Leptospirosis* Report of a Case from South Florida. *Southern Med J* 1945 Dec. v 38 No 12, 811-13 1 fig [11 refs.]

WEBER R. A. & FAVOUR, C. B. *Rat Bite Fever due to Streptobacillus moniliformis treated with Penicillin*. *Bull Johns Hopkins Hosp* 1945 Aug v 77 No 2 132-9 1 chart. [15 refs.]

The record of a typical case of rat bite fever due to *Streptobacillus moniliformis* which was cultured from the blood. In order to exclude a mixed infection with *Spirillum minus* a number of white mice were inoculated with the patient's blood and remained free from infection. On the 13th day of the disease when arthritic symptoms were at their height penicillin in doses of 8 000 units administered intramuscularly every two hours was started and continued for two days followed by 6 000 units every three hours for the next ten days. Blood cultures following treatment were negative and the arthritic symptoms gradually improved and disappeared within a month after the completion of treatment.

The patient has remained without any recurrence of symptoms for more than a year [See also this *Bulletin* 1945 v 42, 811]

The growth of *Streptobacillus* from the patient's blood was found to be inhibited by as little as 0.001 unit of penicillin per cc. in media which normally supported luxuriant growth.

LEPROSY

CASARIAN T. Contagiousness of Leprosy *Acta Med Orientalis (Palestine & Near East Med J)* 1945 June v 4 No. 6 181-4. [12 refs.]

The author gives information regarding the incidence of leprosy in Palestine and discusses the reasons for the low degree of contagiousness of this disease basing his remarks on 36 years' experience at the Jesus-Hill Leprosarium. None of the seven nursing sisters who worked at the institution for 13 to 33 years contracted the disease. Only 26 per cent of the leprosy patients admitted were known to have infected relatives and children of lepers brought up in a separate building did not develop the disease. The author states that every case of leprosy owes the infection to direct or indirect contact with another but that infection takes place only with difficulty owing to the low degree of virulence of Hansen's bacillus and that new infections are rare after the age of 30 to 35 years. During the last 70-75 years the number of cases in Palestine has fallen from 220-250 to 120-150.

DEGOTTE, J. Nouvelle contribution à l'épidémiologie de la lèpre. Étude comparative de la chefferie de Makoda 1939-1943 [The Epidemiology of Leprosy—a Comparative Study in 1939 and 1943 in Makoda.] *Rec Travaux Sci Méd Congo Belge* 1945 July No. 4 70-81 3 maps & 1 graph.

This paper reports on a comparative study of the incidence of leprosy in 1939 and 1943 in a north-western area of the Belgian Congo the mean altitude which is 800 metres. It consists mostly of grassland, with comparatively leprosy incidence and some forest areas with higher rates. In 1939 15,528 and in 1943 16,106 of the inhabitants were examined, and infection rates of 4.33 and 4.25 per cent respectively were found indicating a slight decline in the disease. The incidence in different divisions of the area examined varied from 2 to 6 per cent. The number of new cases found in 1943 amounted to 210 the highest incidence being found in persons aged 30-40 there was also a high rate among a few persons over 60. A table is given of cases classified according to the Cairo Conference system. It is stated that the majority of the lepromatous cases have been effectively segregated, and the author deduces that the occurrence of about as many new cases in the area under observation during the four years under consideration as for leprosy in general proves that neural leprosy is contagious. [If the segregation of the infective cases was carried out at or about 1939 the occurrence of a number of new cases during the next four years may largely be the result of infections which took place before the infective cases were segregated—the incubation, or latent period of leprosy is often of several years' duration before the first symptoms appear.]

L. Rogers.

TROUT C. L. Agglutination Test with the Leprosy Bacillus. *J Trop Med & Hyg* 1945 Aug Sept. v 48 No 4 73-4

In this short note the results are reported of the use of an antigen prepared from cultures of a pleomorphic acid fast bacillus obtained in California called the Rethu bacillus and one prepared from *Mycobacterium leprae* separated from lepromata. One vaccine contained a toxin filtrate taken from a milk culture of the Rethu organism and a second a similar substance from a broth culture. Sera taken from ten persons vaccinated with these products in 1 cc. doses weekly for six doses agglutinated leprosy bacilli taken from lepromata. Attempts were therefore made to immunize the children of lepers and others who had associated with lepers by means of these vaccines which produced temperatures as high as 103 F in control patients but seldom a rise above 100°F in lepers. The Rethu vaccines sterilized by 1 per cent formalin were also used for treatment in a group of lepers and the author has the impression that the milk culture toxin-filtrate was the more effective both for treatment and prophylaxis but it is too soon to form conclusions.

CHORINE V. Nouvelle réaction de floculation de la lèpre [A New Flocculation Reaction in Leprosy] *Médecine Trop. Marseille*. 1943 Nov Dec. v 3 No 6 419-48 5 graphs [13 refs] Also in *Ann. Inst. Pasteur* 1944 Sept Oct & Nov-Dec. v 70 Nos 9/10 & 11/12 257-76 341-56 5 graphs [13 refs]

These two references refer to the same paper. It gives full details of a comprehensive investigation of a flocculation reaction of diagnostic value on the lines of the Rubino reaction which consists in the sedimentation of formalized red corpuscles of the sheep and of Westergren's measurements of the rapidity of sedimentation of non formalized red corpuscles. Formalized red cells sediment more quickly than unformalized cells in the presence of the serum of a leprosy subject. Chorine has sought to isolate the active principle of formalized cells by preparing extracts of formalized blood or tissues and using the extract as an antigen. After trying a number of chemicals he found that 90 per cent alcohol was the best solvent of the antigen for full details of the preparation of which the original paper should be consulted by those interested in its use.

In using this test 1 cc. of the antigen is poured into 2 cc. of double distilled water and mixed at a speed of 200 revolutions per minute at the end of which 8 cc. of distilled water are added. The optical density is measured by photometry and the reaction is calculated as the difference between the degree of density found for the curve of an emulsion with the serum to be tested and that of a mixture with distilled water only. A series of tubes is put up with increasing proportions of the serum and decreasing proportions of antigen to allow curves to be plotted. A series of illustrative curves under different conditions of the numerous experiments is given in the paper from which the following conclusions are derived. The sera to be tested should be heated for 30 minutes at 55°C. The reactions should be carried out at a temperature of 25°C for 4 hours. This may necessitate a cooling apparatus when working in the tropics. The antigen is best used in a dilution of 1 in 10 and within half an hour of the preparations of suspensions of it. The sera should be kept before use at a temperature of 4°C at which they can be kept for 4 or 5 days. Three series of four tubes each are put up. In the 4 tubes of the first series 0.15 cc. serum in the second series 0.20 and in the third series 0.50 cc. are placed. In each of these series the first two tubes are filled up to 1 cc. with the suspension of the antigen. The remaining two tubes are filled up to 1 cc.

with alcoholized water these are control tubes. They are mixed well and kept at a temperature of 25°C. for four hours before the densities of the flocculation are read. The result of the reaction is obtained by subtracting the photometric degree of the control tube from that of the reaction tube.

Tables are given of the data obtained in 200 cases of leprosy and in 100 controls. A difference of over 30 in the densities between the control tubes and those showing the reaction of leprosy sera is considered to be a positive reaction: for only 6 of the 100 controls gave figures up to 30-35 and 2 of 35-40. On the other hand only 10.5 per cent. of leprosy sera gave figures below 30 and in 21 the figure exceeded 200. Feeble reactions indicated by figures of 30-35 numbered only 18.5 per cent. and very intense reactions of over 100 also numbered 18.5 per cent. The low reactions were chiefly met with in slightly affected or stationary cases and in those which had much improved under treatment. High figures occurred during lepra reactions and in advanced cases with nodules. In general tuberculous cases gave low degrees of reaction as compared with lepromatous cases. This new reaction thus appears to be of both diagnostic and prognostic value.

FLOCH H. & DE LAJUDIE P. Sur la lèpre et les intradermo-réactions à la lépromine (Mitsuda) et à la lépromine (Souza Araujo) en Guyane Française. [The Intradermal Reactions to Lepromine and Leprolin in Leprosy in French Guiana.] *Institut Pasteur de la Guyane et du Territoire de l'Inini* Publication No 97 1945 Jan. 15 pp. [24 refs.]

The authors have used both leprolin, supplied by Professor de Souza Araujo and lepromin prepared by the method of Hayashi in their tests on 88 cases of leprosy. Positive Mitsuda reactions were obtained in 90 per cent. of tuberculoid, in 51 per cent. of nerve in 9 per cent. of mixed cases but in none of 10 lepromatous patients. In controls not infected with leprosy reactions were negative in those aged 8 to 9 years but positive in four of eight persons aged 10 to 14 years. With the use of the Souza Araujo's leprolin, similar results were obtained in lepromatous and mixed cases but in only 27 and 23 per cent. respectively in tuberculoid and nerve cases.

TAYLOR, C. E. Leprosy of the Large Intestine and Gall-Bladder. Case Report with Review of the Literature. *Trans Roy Soc Trop Med. & Hyg* 1945 Oct. v 39 No 2, 125-32, 5 figs. on 2 pls. [17 refs.]

The author points out that the gastrointestinal and biliary tracts are among the few parts of the body generally supposed to escape involvement in leprosy but they now report changes in these tissues in a fatal lepromatous case in a West Indian Negro with both skin and nerve lesions. The gall-bladder showed a thickened mucosa with a mosaic pattern due to thickened patches which, on section, revealed a few leprosy bacilli. Similarly the large intestine showed thickening of the mucous membrane with large ulcers in the lower portions and smaller ulcers in the upper parts, in the inflamed and oedematous margins of which both scattered and clustered acid-fast lepra-like bacilli were found. The patient had died during an active lepra reaction accompanied by diarrhoea. The macroscopic and microscopic characters of the lesions are illustrated.

MONTEL, R. & BASSET. Deux cas d'infantisme lépreux. [Two Cases of Leprotic Infantism.] *Bull. Soc. Path. Exot* 1944, v 37 Nos 11/12, 332-7 3 figs.

AGENT G. H. & POGGE R. C. The Therapeutic Effect of Promin in Leprosy
Pub Health Rep Wash. 1945 Oct 5 v 60 No 40 1165-71 8 figs on 2 pls

This paper records further trials of promin in leprosy in continuation of those reported in November 1943 [this *Bulletin* 1944 v 41 494].
 The present report is based on the treatment of 137 patients at the U.S.A. National Leprosarium by means of 32 000 intravenous injections amounting to a total of 128 861 gm. The average daily dose including days of rest varied from 0.4 gm. to 4.6 gm. The usual dosage is 1 gm. daily increasing to 5 gm. but in some patients who showed toxic reactions the maximum daily dose did not exceed 2 gm. The present routine consists of 2 to 5 gm. daily by the intravenous route on six days each week in courses up to two weeks with a week's rest between the courses which allows of restoration of the red corpuscles lost during a course. The longer the duration of the treatment and the larger the doses the greater the benefits as shown by tables of data. The percentage of the total 137 patients treated who improved was 58.4 the figures for treatment of less than six months and for more than six months respectively being 25.6 and 71.4 per cent. All of six cases treated for 3 to 4 years had improved. A total dosage of less than 500 gm. only produced improvement in 25.6 per cent but with 500 to 1 000 gm. the percentage rose to 72.5 per cent. or nearly three-fourths of the patients. Only two patients became worse while under treatment both were advanced cases with involvement of the larynx. The improvement was objective and not only subjective this is confirmed by photographs of patients with advanced lepromatous disease before and after treatment the benefits are not limited to action against secondary infections. In over 10 per cent. of 62 patients treated for more than one year positive bacteriological findings have changed to negative on several consecutive monthly examinations. Serological reactions may also become negative coincidentally with improvement in or arrest of the disease as shown by tables of data. The cost of the drug is not given. Promin is not claimed to be a specific remedy for leprosy but there is evidence that it has at least an inhibitory effect on the progress of the disease and that it even causes retrogression in some lesions. There is therefore some hope that continued chemotherapeutic research may produce a still more effective remedy. Preliminary studies suggest that diosone has a similar action to promin and that it may prove even more effective.

GUICHARD F Préparation directe en partant des graines des esters d'*Hydnocarpus anthelmintica* Pierre en vue du traitement de la lèpre [Préparation of Esters of *H. anthelmintica*.] *Bull Soc. Path. Exot* 1945 v 38 Nos 1/2 9-12

The author points out that most methods of preparing the soaps and ethyl esters of the fatty acids contained in the oils used in the treatment of leprosy are laborious and he describes a simpler method in which the fatty acids contained in the seeds are dissolved without transformation in an apparatus containing absolute alcohol and sulphuric acid. The seeds are sterilized in an autoclave and decorticated. The kernels are scorched, kept at 100°-110°C. for a night before being pulped, and are then mixed with one third of their weight of sandstone in fine grains to facilitate the penetration of absolute alcohol to which 5 gm. sulphuric acid per 100 cc. has previously been added. The amount of acid-alcohol is equal to the weight of the pulped kernels. Some grains of pumice-stone are added and heat is applied. The results of distillation are collected over a period of ten hours. The products are treated with 15 per cent. chlorinated water several times washed twice with distilled water and neutralized with a

small quantity of anhydrous sodium carbonate to purify the esters. To preserve them 2 gm. per cent. of anhydrous sulphate of soda is added to each full well-corked container. Before placing in ampoules 1 per cent. gulacol is added and the ampoules are sterilized at 115 C. for 15 minutes. The esters thus prepared keep well and are well borne by the patients. *L. Rogers.*

MONTEL, R. La méthode de Charpy dans le traitement de la lèpre. [The Treatment of Leprosy by Charpy's Method.] *Bull. Soc. Path. Exot.* 1945 v 38 Nos 3/4 63-4

Charpy's method of treating lupus is as follows: vitamin D 15 mgm. three times during the first week of treatment twice a week during the next three weeks and once a week during the next four months; calcium gluconate by intravenous injection of medium doses three times a week, and a litre of milk daily are given for the same period. The author has tried this treatment in two cases of leprosy.

One patient suffering from nodular leprosy and already much improved by treatment with methylene blue and chaulmoogra, showed considerable further improvement under the Charpy method: the paratubercled monocytes decreased in number, the lepromata and leprosy infiltrations diminished markedly in size and the patient's bodily state improved.

The other patient suffering from trophic leprosy showed remarkable improvement in his general condition: increase of weight and decrease of nerve pains.

The author thinks that these results are encouraging and that further trials of the method should be made. *J. F. Corson*

HELMINTHIASIS.

ALVES W. & BLAIR, D. M. Schistosomiasis. Intensive Treatment with Antimony. *Lancet.* 1946 Jan. 5 9-12.

In a preliminary communication one of the authors [this *Bulletin* 1945 v 20 815] has already recorded the satisfactory result of rapid intensive treatment of schistosomiasis with antimony. In this paper the authors record in more detail similar treatment of 100 cases of *S. haematobium* and *S. mansoni* infections chiefly in African soldiers. Basing their investigations on the work of CHARGIE and his collaborators (*J. Amer. Med. Ass.* 1935 v 104 878) which led to the intensive arsenical therapy of syphilis with intravenous drip transfusion (HYMAN *et al.* *ibid.*, 1939 v 113 1208) [see also *Bulletin of Hygiene* 1940 v 15 234] and later to the therapeutically more effective "multiple syringe injections" (EAGLE and HOGAN quoted by COLE *et al.* *Bulletin of Hygiene* 1944 v 19 104) the authors found that continuous intravenous injections of 100 cc. of a 1 per cent. solution of sodium antimonyl tartrate in 5 per cent. glucose-saline caused excruciating phlebitis. They abandoned this technique for the multiple syringe method, giving intravenous injections three times daily at three-hour intervals for two days—a total of six injections, given at 9 a.m., 12 noon and 3 p.m. on each of two consecutive days. The preparation of antimony employed was sodium antimonyl tartrate and the amount of drug injected at each dose was usually 1 grain or 2 grains.

Each injection was made in 10 cc. of 5 per cent. glucose saline into a vein in the antecubital fossa and given steadily at a rate not exceeding 2 cc. per minute. At least five minutes were therefore taken for each injection, and the

authors stress the point that *This slow and steady injection of the drug is of fundamental importance in the success of the treatment*. In no case have toxic reactions led to interruption or discontinuance of the course and the absence of the more troublesome manifestations usually associated with the intravenous administration of antimony was striking. Cough resulted in only 16 of the 100 cases during or more commonly after the first injection and never lasted more than two minutes. The frequency of its occurrence diminished through the course and only two patients suffered from it as a result of their sixth and final injection. Vomiting did not occur in association with the second but was encountered in six cases and two cases respectively with the fifth and sixth injections. In the 100 cases a feeling of constriction of the chest was noted by one asthmatic patient only. Abdominal cramps occurred in three cases there were no rheumatic pains and no collapses. Salivation was common after the early injections but usually vanished by the second day. The average rate and the regularity of the pulse in the whole series was not altered by the antimony dosage. In two cases there was a brisk haematuria after the third injection but in neither did it persist. In one there was a drug rash of limited distribution appearing 24 hours after the last injection and persisting for one week. A striking feature in many cases was a state of euphoria the day after the conclusion of treatment. This could not be ascribed to relief as the African does not as a rule fear injection treatment and it was noticed both in Europeans and in Africans.

Data relevant to the 100 cases treated are listed in tabular form showing the species of parasite the degree of eosinophilia, the patient's weight in pounds and the gross dosage of S.A.T. given to each. This gross dosage ranged from 7 grains to 14 grains of S.A.T. and is based on the body weight roughly one grain of S.A.T. being given for each 12 pounds of body weight. A man of 144 pounds would, therefore get a gross dosage of 12 grains of S.A.T. The individual doses six for each individual were worked out for the sake of economy and convenience so that as often as possible 1 grain or 2 grains were given. For example (doses in grains) —

	9 a.m.	12 noon	3 p.m.	9 a.m.	12 noon	3 p.m.
Patient A gr 10 S.A.T. given as	2	2	1	2	2	1
Patient B gr 13½ S.A.T. given as	2	2	2½	2½	2½	2
Patient C gr 9½ S.A.T. given as	2	2	1	2	1½	1

The authors record their use of an intradermal test in diagnosis. The test was performed with a cercarial antigen and its development and application are to be described in another communication. This test was used in initial diagnosis which was confirmed in each case by the examination of urine and of stools for schistosome ova. The skin test had become negative in a big proportion of the cases retested two months after treatment and where this reversion took place the authors regard it as indisputable evidence of the death and dissolution of the worms. In none of the 100 cases treated were schistosome ova found in the stools or in the urine two months after treatment. Of the 53 cases re-examined two months after treatment only 14 gave a positive skin test. Nine of these 14 were retested one month later six of them had then become negative two remained positive and one originally strongly positive had become only weakly positive. In no case examined two months after treatment were eggs found in the excreta.

In eight cases the urinary antimony excretion was estimated during the course of treatment and for 24 hours afterwards. Data are given in a table showing that between 70 and 80 per cent. (in the average case of this series 8 grains of S.A.T.) of the antimony injected remains in the body 72 hours after beginning treatment and this high concentration of antimony in the body is held by the authors to be responsible for the rapid disappearance of ova and the apparent cure of all their cases.

The authors discuss the obvious economic and public health advantages inherent in their short intensive course of treatment for schistosomiasis and point out its manifold implications in the mass treatment of the populations inhabiting the highly endemic areas of the world. They suggest that intensive antimony therapy may find a place in the treatment of kala-azar, other forms of leishmaniasis and filariasis.

[This important paper may well open a new chapter in the treatment, with the heavy metals, of protozoal and of helminth infections.]

A. R. D. Adams.

MILLS W. G. Treatment of Schistosomiasis. *Lancet* 1946 Jan. 5 12-13.

The author treated 46 cases of *S. haematobium* infestation in West African native troops with daily intramuscular injections of Stibophen (B. W. & Co.) [=Fouadin, Bayer] or of Anthiomaline (M. & B.) for 6 days during each of two successive weeks. He either "cured" or "presumably cured" all but four of the 46 cases. Where he claims cure the bladder was free from all tubercles, ulcers and granulations on monthly cystoscopy for three months after treatment. Presumably cured cases showed cystoscopically a virtually normal bladder on the occasions on which it could be examined, and no clinical relapse was reported. Toxic complications of treatment with either drug were minimal, and vanished, where present, within a week of ending treatment.

In the four uncured cases two developed new crops of tubercles in the bladder within three months of treatment: one had a small contracted bladder and had to be invalided from the army and the last had a severe chronic and relapsing staphylococcal cystitis which also led to his being invalided. The author draws attention to the possibility of late relapses but considers these improbable in his series of cases. He stresses the importance of cystoscopic control throughout the treatment of urinary schistosomiasis.

WARD R. O. Some Surgical Aspects of Urinary Bilharziasis. *Proc. Roy. Soc. Med.* 1945 Nov. v. 39 No. 1 27-38 (Sect. of Urology 1-12) 23 figs. (12 coloured)

This paper presented to the Urological Section of the Society contains a general account of urinary schistosomiasis from the standpoint of a urological surgeon. It contains nothing new and is designed to direct attention to the possible occurrence of schistosomiasis in members of the forces who have served overseas during the recent war. The author stresses the value of cystoscopic examination which may reveal the diagnosis in the apparent absence of cells and of ova from the urine.

OLIVER GONZÁLEZ J BIAGGI \ & RIVERA LEÓN J The Effect of Chlorine on the Motility and Infectivity of the Cercariae of *Schistosoma mansoni* Puerto Rico J Pub Health & Trop Med 1945 Mar \ 20 No 3 357-61 [Spanish version 362-6]

The authors investigated the question as to whether the inactivity of cercariae of *S. mansoni* after exposure to chlorine (calcium hypochlorite) also implies their loss of infectivity. They found that chlorine concentrations of 1.25 to 0.5 parts per million parts of water caused the cercariae to become inactive in the average times of 2.5 to 10.4 minutes but that a concentration of 0.2 part per million had no definite effect. In the infectivity tests rats were exposed for one hour to the cercariae as soon as the latter were observed to be completely inactive. Concentrations of chlorine of 1.25 parts per million for a maximum duration of exposure of four minutes or 0.44 part per million for 18 minutes made the cercariae inactive and non infective. A concentration of 0.22 part per million did not exert a sure effect on the motility of the cercariae and those that apparently showed inactivity at this concentration were still infective to rats.

It is suggested that a minimum period of exposure of 20 minutes to the effects of a chlorine solution yielding a minimum chlorine residual of 0.50 part per million of water may be sufficient to render cercariae of *S. mansoni* non infective.

WELLER T H. & DAMMIN G J The Acid-Ether Centrifugation and the Zinc Sulfate Flotation Techniques as Methods for the Recovery of the Eggs of *Schistosoma mansoni* Amer J Trop Med 1945 July, v 2 No 4 367-74 1 fig [17 refs]

The authors carried out studies designed to evaluate and compare the effectiveness of the acid-ether centrifugation and the zinc sulphate flotation techniques in the recovery of eggs of *Schistosoma mansoni*. Uniform suspensions were prepared of 46 faecal specimens each containing relatively large numbers of *S. mansoni* eggs. 25 were found to contain more than 400 eggs per cc. by the Stoll count. The suspensions were employed in testing the efficiency of four different techniques. Calculations of the percentage recovery of available eggs were limited to the group of 25 suspensions containing more than 400 eggs per cc.

(1) *Acid-ether routine technique*—One cc. of the suspension and 5 cc. of 40 per cent HCl (40 cc. conc. HCl diluted to 100 cc.) are mixed by shaking in a 15 cc. centrifuge tube filtered through two layers of moist gauze and then mixed with an equal quantity of ether. The mixture is shaken thoroughly and spun for 1 minute at 1500 r.p.m. The debris floating at the acid-ether junction is loosened and then the acid and ether layers are poured off and discarded, leaving a few drops of the egg bearing sediment which is decanted on to a slide for egg counting.

(2) *Zinc sulphate flotation with loop removal*—Using 1 cc. of the basic suspension this method is essentially similar to that outlined by FAUST *et al* [this Bulletin 1940 \ 37 62]

(3) *Acid-ether semi-quantitative technique*—This method follows that of (1) up to and through the centrifugation step. Thereafter the ether and acid layers together with the floating debris are removed by pipette and discarded leaving 1 cc. of the acid and sediment. The latter are mixed together and three samples of 0.075 cc. each are withdrawn and prepared for egg-counting. The results of six counts are averaged and the number of eggs per cc. of undiluted faeces is calculated.

JAFFÉ, R. Observaciones sobre lesiones pulmonares producidas por *Schistosoma mansoni* (Su frecuencia y su importancia.) [The Frequency and Importance of Pulmonary Lesions in *Schistosomiasis mansoni*] *Rev. Sanidad y Asistencia Social* Caracas, 1944 Dec. v 9 No 6 1287-68. [13 refs.]

Pulmonary schistosomiasis i.e. lesions due to the presence of ova of *S. mansoni* in the lungs is far from uncommon—the author found them in 12 out of 50 cases examined—but only rarely (2 per cent. of autopsies) are the lesions extensive enough to produce changes visible to the unaided eye. SHAW & GHARKE have noted them in 33 per cent. of cases in Egypt and KORFISCH in 64 per cent. of 147 examined in Porto Rico. Dew thinks that this condition is more common in infestations by *S. haematobium* than in those by *S. mansoni*.

Four questions arise from this association. (i) In what proportion of cases of schistosomiasis do we find this pulmonary involvement? As stated above the author found it in 12 out of 50. (ii) How often are these lesions the result of the presence of the worms or their ova extensive enough to cause confusion with other diseases such as tuberculosis? This is not answered, as data are insufficient. If the nodules are few the chances of this confusion arising are slight but if grouped, as they sometimes are they may cause confusion unless more detailed investigation is made. (iii) Is there evidence of involvement of organs other than the lungs in these cases? Yes the ova may be seen in the portal radicles and the parasites and their ova in the liver and elsewhere. (iv) Is there any connexion between pulmonary schistosomiasis and tuberculosis of the lungs in the sense that either predisposes to the other? The author arrives at a negative conclusion, finding that tuberculosis is no more common in schistosomiasis patients than in the general population. The tubercles found in schistosomiasis do not contain any *Mycobacterium tuberculosis* and are "pseudo-tubercles" unless the word is used purely generically.

Apart from these considerations the lesions may be so extensive as to give rise to chronic interstitial pneumonia if sparse not enough to cause any serious symptoms but, if widespread, enough to cause secondary cardiac embarrassment [see this *Bulletin* 1938 v 35 665].

In conclusion the author is of the opinion that these pulmonary lesions of schistosomiasis have as a rule little if any importance and are rarely sufficiently serious or widespread to cause symptoms but at the same time when radiological examination of the lungs shows small scattered nodules the possibility of schistosomiasis pulmonum should be borne in mind. *H. Harold Scott.*

BANG F. FERGUSON M. S. HARTSTON N. G. & GRAHAM, O. H. Hyperendemicity of *Schistosoma japonicum* on Leyte Island, P.I. *Amer. J. Trop. Med.* 1945 Sept. v 25 No 5 407.

Ova of *Schistosoma japonicum* were found in the faeces of 80 per cent. of native children over 10 years old in the eastern side of the island of Leyte in the Philippine Islands as only a single examination, followed if negative by a second examination after sedimentation of a portion of the faeces was made in each case, the authors infer that everyone in the endemic areas becomes infested before reaching the age of 15 years. The incidence was less in adults than in children, the difference being statistically significant and this suggests that immunity may be developed. *J. F. Corson.*

MAGATH T. B. & MATHIESON D. R. Infection of Wild Rats on Leyte with *Schistosoma japonicum*. *U.S. Nav. Med. Bull.* 1945 Dec. v 45 No 6 1195-202.

It is well known that the endemic area of human infestation with *Schistosoma japonicum* in Leyte Island in the Philippine Islands is limited to the

Leyte Valley, which is about 25 miles long and 8 miles wide and is situated on the east side of the island.

Wild rats in this island appear not to migrate much but to remain throughout their lives in one relatively small area. It was thought therefore that an investigation of the incidence of infestation in these rats might give more information in relation to certain bodies of water and to the distribution of the snail *Schistosomophora quadrasi* than the examination of man and his domestic animals would, especially in the disturbed conditions caused by the war.

Rats were trapped in various localities 163 altogether being caught. They comprised Polynesian rats (10) Norway rats (14) and Black rats (139) the subspecies being undetermined. They were caught in the following places (the numbers infested are shown in brackets): Santa Fé Tacloban 58 (0) Palo 43 (11) Gacao 41 (37) Dagami 7 (4) Santa Fé 12 (10) Alanglang 4 (2) San Antonio Samar 6 (0) Jinamoc Island 2 (0) Total 163 (84).

Infested rats always had eggs in the posterior central lobe of the liver and next in frequency were the eggs found in the faeces and the rectal wall in only two cases were eggs found in the female worm to enter so vessels of the rat's intestine are too narrow for the spread of the disease but that it might be used to define a limited area in which *S. japonicum* is being spread and that the proportions infested might indicate the intensity of infestation of other hosts in the area.

JOHNSON A. S. Jr & BERRY V. G. *Axiatic Schistosomiasis* Clinical Features, Sigmoidoscopy Picture and Treatment of Early Infections. War Medicine Chicago 1945 Sept. v. 8 No. 3 156-62 5 figs. J. F. Corson

Schistosoma japonicum infestation of man occurs in China Japan Formosa the Celebes and the southern Philippine islands of Mindanao Samar and Leyte. The authors record their observations on and treatment of a group of 42 cases in the last named island admitted to the station hospital in the early stages of the disease. In all these patients ova of *S. japonicum* were recovered from the stools after a history of previous exposure to probably infected water. In four cases the duration of infection before the finding of eggs in the stools was determined as 30 35 40 and 44 days respectively. In the 38 others it ranged from 30 to 71 days before the manifestation of symptoms.

The authors describe in some detail the mode of onset symptoms and signs and the investigations they made in their cases. The only constant physical sign was a tender palpable liver. Pathognomonic lesions could be seen sigmoidoscopically in 67 per cent and biopsy of the distinctive small yellow nodular lesions found particularly at the recto-sigmoid junction revealed ova. The lesions are so characteristic that routine biopsy is unnecessary.

Twenty two patients were treated with the usual course of potassium ammonium tartrate and 20 with Fouadin. The former gave rise to the usual side effects the latter to none. The cure rates have not yet been established, but therapy resulted in clinical improvement a fall in the average eosinophil count and the disappearance of ova from the stools.

LARRH J. E. Jr *Effects of Alcohol on Natural Resistance to the Dwarf Tapeworm in Mice* *J. Parasitology* 1945 Oct. v. 31 No. 5 291-300 [16 refs.] A. R. D. Adams

BARNETT L. Progress in our Knowledge of Hydatid Disease. With some Contributions thereto from the Otago Medical School. *New Zealand Med J* 1945 Dec. v 44 No. 244 304-8 2 figs.

An interesting summary of work on hydatids by the Chairman of the Hydatid Research Committee. He stresses the fact not sufficiently recognized, that primary peritoneal cysts are rare less than 1 per cent. of the whole they are nearly always secondary to cyst of the liver which has escaped notice for cysts of the dome of the liver may grow slowly for 30 years or even longer before producing signs of ill-health. Also the vast majority of primary cysts arise in childhood, and the aphorism that "a hydatid cyst is nearly as old as its host" is generally true. Biliary colic and jaundice may be caused by a cyst opening into the bile-ducts this is not rare and in hydatid countries should always be borne in mind.

The author makes some observations on operative details indicating his preference for the abdominal rather than the lower thoracic route for cysts of the dome, for these cysts are usually old and degenerated and contamination and sepsis occur twice as frequently after transthoracic as after the abdominal operation.

Lung cysts in the young should be given the chance of spontaneous cure unless there are indications of sepsis and toxæmia. The danger of tapping is duly noted. [The abstractor had a sad experience of this more than 50 years ago when as house physician, he was directed to aspirate a "pleural effusion". When the aspirator was thrust in the patient died in a few seconds drowned in the fluid the cyst-wall had ripped up and the lung was flooded with the fluid which autopsy showed to be hydatid.] Brain cysts when primary nearly always occur in childhood if in an adult a brain cyst is probably secondary to cyst of the heart.

Study of the hexacanth embryo leads the author to conclude that the central pair of spirules is used for penetration of tissues and the lateral pairs for propulsion. The size of the embryo has been variously recorded the author finds it to be 28 μ long by 25 μ broad, and the whole ovum 41 by 34 μ . Again, contrary to the fairly general idea that the gastric juice of the host acts on the egg-shell to liberate the embryo he believes (with DÉVÉ and others) that hatching takes place in the small intestine where the contents are alkaline.

There is probably a high degree of innate immunity in dogs to hydatid infection, otherwise infection would be much more prevalent than it is at the same time if experiments now in hand succeed and immunity can be artificially conferred on dogs and lambs this will go a very long way towards the control of hydatid in the country.

FLOCH H. & DE LAJUDIE P. Sur la filariose à *W. bancrofti* en Guyane Française, la lymphangite endémique et l'éléphantiasis des pays chauds. [Filariasis due to *Wuchereria bancrofti* in French Guiana. Endemic Lymphangitis and Elephantiasis of the Tropics.] *Institut Pasteur de la Guyane et du Territoire de l'Inini Publication No 109* 1945 Aug. 17 pp. [23 refs.]

Thick blood films taken from the finger at 3 p.m. and between 9 and 10 p.m. from natives of French Guiana and others were stained with Giemsa's stain and

examined for microfilariae. These were present in 27 (12.4 per cent.) of 217 males and 20 (18.1 per cent.) of 110 females. In cases where a specific diagnosis was difficult the microfilariae were identified by measurement all were diagnosed as of the species *Wuchereria bancrofti*. The authors have not found the embryos of *Filaria azarai* (demarquayi) or *Acanthocheilonema perstans* in natives of French Guiana. The aetiology of tropical lymphangitis and elephantiasis is discussed and the authors subscribe to the view that they are caused by streptococcal infection.

RUFFIN H & THOMPSON K J. Structural Changes in Early Filariasis. *Arch Pathology* 1945 Oct. v 40 No 4 220-24 5 figs J F Corson

This account is based on a study of 30 cases. Some of the patients had been stationed in South Pacific islands where filariasis is endemic others showed signs leading to suspicion of filarial infestation. Eighteen of them had blood eosinophilia of 6-11 per cent. in others the percentage did not exceed the normal and the total red and white counts were within normal limits. No organisms such as streptococci were found in any of the lesions. In most the first symptoms were a painful enlarged lymph node a brawny lymphangitis or an acute epididymo-funiculitis. In 12 the genitalia or lower limbs were primarily involved in 9 the upper limb and in 9 the upper and lower limbs at the same time. Presence of the filaria was demonstrated in 6 of the patients in the others though the worms were not found the histological picture was to all intents and purposes the same.

The essential changes comprised marked hyperplasia of the related lymph follicles with mitotic figures at the germinal centres and general infiltration with eosinophilia. The lymphatic channels showed fluid lakes of the pink-staining albuminoid fluid. The histological changes were dilatation of the lumen of the lymphatics with necrotic debris thickening of the wall and eosinophilic infiltration with epithelioid cells fibroblasts and multinucleated cells of the Langhans type. Three cases are detailed—in men of 23, 25 and 29 years respectively—and a plate of six photomicrographs illustrates these changes so far as uncoloured photographs can do so.

The author summarizes the changes in these words. There appear to be three stages in the genesis of filariasis (i.e. the local tissue reaction to infestation) first the acute stage manifested by a typical allergic reaction which may be local or systemic second the subacute or early chronic stage characterized by the development of a proliferative granulation tissue and occurring in lymphatic tissues harboring the parasite third the late chronic stage of the disease typified by a non specific fibrous tissue overgrowth. As in all classifications no distinct delineation is possible. One stage merges imperceptibly into the other.

It is noteworthy that a large proportion of the patients became infested without presenting any symptoms at all events any at present recognizable.

DEHAYAUDE R. G. Microfilarial Granuloma of the Spleen. *Observations in Twelve Additional Cases*. *Arch Pathology* 1945 Oct. v 40 No 4 275-8 8 figs on 1 pl H Harold Scott

This article may be regarded as confirmatory or supplementary to that published in 1942 by the author and B M AMIN on the same subject [see this Bulletin 1942 v 39 707] in which 11 such cases are considered. The present record brings the total to 23. Taking all together the ages of the subjects ranged from 6 to 70 years but 20 were between 25 and 50 years. 5 were females (44).

18 were males. In 10 of the present series however living specimens of microfilariae were obtained from the splenic granulomata whereas in the previous 11 the description was made from fixed tissues. Obtaining them alive has enabled a definite diagnosis of *B. bancrofti* to be made. Prior to this there had been a suspicion that it might be the Malayan filaria. Even when microfilariae are not seen the histological structure is the same (except that the lymphocytes eosinophiles and giant cells of early granulomatous reaction had disappeared) and represented a later fibrosed condition of a granulomatous lesion. The macroscopic features the author avers are so definite that mere inspection enables one to say that the lesion is of microfilarial genesis.

H. Harold Scott.

CULBERTSON J. T. ROSE H. M. & OLIVER-GONZALEZ, J. The Chemotherapy of Human Filariasis by the Administration of Neostibosan. Second Report. *Amer J Trop Med.* 1945 Sept v 23 No 5 403-6

Bancroftian filariasis although it has proved a smaller military problem than was expected is widespread in the native populations of certain areas. Measures of protection adequate for military personnel are inadequate for civilian communities. A satisfactory and specific treatment of the infected would constitute a significant step in solving the practical problem of human filariasis.

The authors have already published one report on the use of neostibosan as a therapeutic agent in this infection [*this Bulletin* 1943 v 43 54] the present paper constitutes a second report on the progress of the cases therein recorded twelve months after the end of treatment. Data are given in two tables of the 30 native Porto Ricans infected with *Wuchereria bancrofti* and treated with neostibosan, and of the 15 untreated controls similarly infected.

The treated cases received three intravenous injections of neostibosan on alternate days the first being 50 mgm. the second 100 mgm. or 150 mgm. and the third 300 mgm. of the drug. Thereafter 300 mgm. were given daily or on alternate days for 33 or 48 days. The microfilariae were counted in 60 cmm. of dried and stained nocturnal finger blood at least monthly for 9 to 14 months after treatment.

The authors give the following summary —

"Thirty patients infected with *Wuchereria bancrofti* were treated with neostibosan for from 33 to 48 days. After twelve months 13 of the patients were free of circulating microfilariae and 5 others had lost from 67 to 99 per cent. of their embryos compared with the number in the blood before treatment. The twelve remaining patients showed little promise of eventual eradication of their infections after observation for nine months.

Of 15 control untreated patients infected with *Wuchereria bancrofti* all remained infected for 14 months of observation. In this interval, 12 showed an over-all increase and 3 showed a decrease in the number of circulating microfilariae.

Among the treated patients some of whom had been free of microfilariae for 12 months none presented untoward symptoms referable to treatment.

HUMMELEN L. R. Helminthiasis bij kinderen in het bijzonder binnen het schoolartsdistrict Huizen [Helminthiasis in Children, particularly in the School Medical Officer's District of Huizen.] [Thesis for Doctorate of Medicine University of Amsterdam 30 Nov 1945] 86 pp 1 pl [Numerous refs.] English summary 87-91 1945 Zutphen J B van den Brink & Co

The author examined the faeces of 1 708 schoolchildren in towns and villages of the district of Huizen to the south-east of Amsterdam for worm eggs there were about equal numbers of children of each sex. Ova of *Ascaris lumbricoides* were found in 14.6 per cent of children in 12.2 per cent, and of both species in 4.9 per cent altogether 22 per cent. of the children showed helminth infestation. In different places *Ascaris* infestation varied from 0.9 to 48.7 per cent *Trichuris* from 2.9 to 38.8 per cent, and double infestation from 0 to 17 per cent altogether the percentage varied from 0 to 52.7. Ova of *Taenia* and *Ancylostoma* were not found.

In addition a similar examination was made of 100 schoolchildren of Amsterdam and of 104 of West Terschelling in the former the figures for *Ascaris* and *Trichuris* were 0 and 3 per cent respectively and in the latter they were 35 and 84 per cent respectively.

The degree of infestation depended on the state of local hygiene it was greater in the poorer classes and in rural than in urban communities. It was found that vegetables grown for food were manured with human faeces. Few symptoms were caused and body weight was not affected nor apparently was the intelligence of the children.

The faeces of the same 1 912 children were also examined for ova of *Enterobius* in different localities the rate of infestation varied from 3 to 28.1 per cent average 10.5. A further examination of 1 060 children was made with the glass pestle method of SCHUFFNER and SWELLENGREBEL [this *Bulletin* 1945 v 42 922] and rates of infestation varying from 72 to 100 per cent average 85.2 were found. The high percentage of *Enterobius* infestation is considered to be due to reinfection.

The author considered that the schools did not play a part in the spread of *Ascaris* and *Trichuris* infestation but that they did in the case of *Enterobius*. Fifty five children infested with *Enterobius* were treated with gentian violet—eggs of the last species were found in the dust of a sanatorium. 5 mgm. for each year of age three times a day for a week then a week's interval and then the same dosage repeated for another week. The rate of infestation was reduced to about half but after 8 weeks it had again risen to 98 per cent. The author does not recommend mass treatment of schoolchildren with the anthelmintics at present available.

PEPPER, O. H. P. & DIAZ RIVERA, R. S. Trichiniasis. A Review of the Clinical Picture and Laboratory Diagnosis of the Disease, with an Analysis of several Cases. *Puerto Rico J Pub Health & Trop Med.* 1945 Mar., v 20 No. 3 367-76 [Refs. in footnotes.] [Spanish version 377-83.]

In this useful brief survey of trichiniasis the authors bring out well the variety of the possible symptoms and the difficulty which may be encountered in diagnosis. Most of the information given is available in textbooks. After a survey of the American and Spanish literature the authors are impressed by the tremendously high incidence of trichiniasis recorded in some countries of temperate zones in comparison with the tropics where trichiniasis seems to be relatively rare. They are unable to account for this difference, but suggest that it may be due to the greater efficiency of investigation done in the United States and to differences in diet. In the tropics people are so poor that they eat less meat and more carbohydrate and they cook their food more thoroughly (especially those of Spanish descent). Also when diarrhoea and eosinophilia occur together in the tropics they may be ascribed to intestinal parasites without examination for *Trichinella* being made. The apparently low incidence of trichiniasis in the tropics should be investigated further. The authors remark upon the fact that trichiniasis has not yet been recorded from Porto Rico although large quantities of pork products are eaten there and most of these are imported from the United States where DICKMAN [*Bulletin of Hygiene* 1938 v 13 729 found, in Philadelphia, *Trichinella* in 10 per cent. of pork sausage picked at random in the meat markets. The incidence of trichiniasis in the United States determined by post-mortem examinations is 10 to 25 per cent.

The brief description of the clinical picture emphasizes the great variety of " " may be encountered [see also recent abstracts in this *Bulletin*]. The diseases simulated include meningitis polyomyelitis, encephalitis polyneuritis periarthritis nodosa, tetanus (when the masticatory muscles are involved) typhoid fever scarlet fever German measles and *erythema multiforme*. The authors make the somewhat unorthodox statement that the diaphragm and muscles of the thoracic and abdominal walls are less frequently involved than the gastrocnemii deltoid, biceps and muscles of the eye. For diagnosis they rely upon demonstration of the larvae in the blood, cerebrospinal fluid and muscles and they regard eosinophilia as of great diagnostic value. They demonstrate the larvae in the blood (during the early invasion period) by diluting 5 to 10 cc. of venous blood with 2 per cent. acetic acid and examining the sediment. The cerebrospinal fluid is centrifuged and the deposit examined [cf GAASE, this *Bulletin* 1945 v 42, 481 for the presence of antibodies in the cerebrospinal fluid]. Eosinophilia is not a measure of the severity of trichiniasis because it may be very low in the more acute cases [cf GAASE, this *Bulletin* 1948 v 43 236]. It is a drawback of the precipitin test that it does not become positive until the fourth week. Discussing the limitations of the Bachman intradermal test, the authors say that it sometimes fails in cases of

proved trichiniasis and that in others the reaction is delayed group reactions with other parasites occur and some normal people may give false positives [cf recent abstracts in this *Bulletin*]

The authors record brief details of eight subjects. The first shows the simulation by trichiniasis of an acute abdominal emergency the second its simulation of nephritis and tetanus the third involvement of the eyes and their muscles the fourth the infestation of four youths from the same source (pork) the fifth myocardial damage the sixth extreme myositis the seventh the possible association of trichiniasis with angioneurotic oedema and the eighth its co-existence with asthma.

OLIVER GONZÁLEZ J. Diferencias antigénicas entre la larva y el adulto de la *Trichinella spiralis* [Antigenic Differences between the Larva and Adult of *Trichinella spiralis*] *Puerto Rico J Pub Health & Trop Med* 1945 Mar v 20 No 3 389-418 1 fig [Refs in footnotes]

This is a translation of the author's earlier paper (*J Infect Dis* 1941 v 69 254) (noted by title only in this *Bulletin* 1942, v 39 627). Only the author's main conclusions can be given here some of them have already been mentioned in this *Bulletin* 1944 v 41 225. The author summarizes in the paper under review and in earlier papers [this *Bulletin* 1941 v 38 528] the history of the discovery that when some animals acquire resistance either naturally or by artificial infestation to certain metazoan parasites and, when the living larvae of the parasites concerned (and also the adults of *Trichinella spiralis*) are put into the immune sera thus produced granular precipitates are formed around the external openings of these larvae (mouth anus and sometimes the vulva). The immune sera also have in some instances a parasitocidal action which causes the death and disintegration of the larvae. Precipitates are also deposited in the immune serum.

[BLACKLOCK GORDON and FINE (this *Bulletin* 1930 v 27 880) noted that these precipitates occur in the gut and round the extremities of the larvae of the dipterous insect *Cordylobia anthropophaga* which causes myiasis. They have been since observed around the mouth and sometimes also around the anus and vulva of larvae of the nematodes *Nippostrongylus muris* *Ancylostoma caninum* *Trichinella spiralis* *Strongyloides ratti* and *Ascaris lumbricoides* (see Oliver González this *Bulletin* 1944 v 41 223)]

As a result of his studies of this effect of immune sera of rabbits upon the larvae of *Trichinella spiralis* González believes that these precipitates are formed when the secretions and excretions of the larvae or the adults of this species come into contact with antibodies in the immune serum. In this paper he records his conclusion that two types of antibody one antilarval and the other antiadult appear in the serum of rabbits experimentally parasitized by *Trichinella spiralis* and that these have a specific action against the larvae and adults respectively. He suggests that there may be also a third protective antibody inseparable from the antiadult antibody that this nematode may possess at each phase of its development several antigens and that those studied in this paper are only some of those present.

The antiadult antibody causes *in vitro* (in hanging drops) the formation of precipitates around the mouth anus and vulva of the adult *Trichinella*. The oral precipitate is much the most frequent and appears very quickly. The death of the larvae may result (see below). The antiadult antibody can be detected *in vitro* at the end of about 15 days after the infestation its action increases moderately between the 25th and 35th days and begins to decrease until it ceases on the 50th day. It reappears in full activity on the 5th day

after superinfestation, rising abruptly then, reaching its maximum and continuing to increase when infestations are repeated. It then confers on rats a partial immunity against the intestinal phase of the infestation and passive immunity can be transferred from rabbits to rats.

The anti-larval antibody provokes *in vitro* precipitates around the mouth, but not at the anus of the larva. It appears in the serum on about the 30th day after infestation and attains its maximum action between the 45th and 60th days. Its concentration does not increase but remains moderately high during repeated infestations but it gives hardly any passive immunity to rats. The author therefore suggests that it is the anti-adult antibody which is the decisive factor in the transference of passive immunity from one animal to another (e.g. rabbits to rats). For his reasons for this conclusion the paper itself must be consulted.

The anti-adult and anti-larval antigens described in this paper probably constitute the author thinks complete groups of antigens which acting as groups provoke reactions which are qualitatively different, the differences probably depending on the relative proportions in which the various antigens are present and also on the appearance of new antigens as developmental stages succeed one another. The author claims that Table I shows that the anti-adult antibody but not the anti-larval, is active against immature larvae at the moment when they leave the uterus. This suggests the author thinks that immature larvae have an antigenic structure similar to that of the adults. His studies suggest that this antigenic structure begins to develop when the larvae are 20 days old. As the larvae mature new antigenic structures are developed. These antigenic differences may possibly depend upon the fact that the developing embryos and the adults feed upon the intestinal wall, while the mature larvae feed upon red muscle. In other words the antigenicity of the parasite may be related to the enzyme activity of the special tissue which it parasitizes. The differences observed between the different antigens may perhaps be similar to those shown by some lactobacilli which, by fermenting sugars produce changes in their polysaccharide antigens (see MELCHER, this Bulletin 1944 v 41 225).

González discusses his results in relation to certain general problems of immunity to helminth infestations. He compares his results with those of CAMPBELL (*J Immunology* 1938 v 35 465) who found that in rats infested with the larval stages of *Taenia taeniasformis* two types of antibodies appeared, one produced in the first week of the infestation and able to destroy unencysted larval stages of this tapeworm the other produced when the infestation was established and able to destroy encysted larval stages. González also discusses the work of TALIAFERRO (this Bulletin 1940 v 37 887 1941 v 38 110) on the inability of certain antigens to saturate antibodies. González gives the following possible explanations of the failure of some observers to transfer passive immunity to *Trichinella spiralis* or to observe any deleterious action of immune sera *in vitro* (1) the sera used for transfer of passive immunity were mostly obtained by these observers from animals which had been artificially infested only once and the sera were taken a long time after infestation, or perhaps at the moment when the anti-adult antibody was very scarce in the serum (2) some observers have used the sera of rats and guinea-pigs which produce González thinks antibodies much less powerful than those produced in rabbit serum (3) observations on the deleterious action *in vitro* have been made for 24 hours only which is a very short time for their observation. González made observations for as long as 7 days (4) the movements of the larvae may have dispersed the precipitates in some instances especially when they have not been given sufficient space in the apparatus used. McCOR (this Bulletin 1941 v 38 529) suggested that resistance to *Trichinella spiralis* is

chiefly mechanical the adults being expelled as the result of peristalsis and secretion by the intestinal mucosa of increasing quantities of mucus he doubted the existence of humoral resistance to them. CHANDLER (*Amer J Trop Med* 1939 v 19 309) postulated the existence of a local (intestinal) resistance provoked by antibodies which do not get into the blood in appreciable quantities but are absorbed and retained by certain cells of the intestinal mucosa he thought that this type of resistance may be the most important one in trichiniasis and that the other type of resistance is produced when parasites migrate and liberate antigen into the circulation so that antibodies are produced there TALIAFERRO [this *Bulletin* 1934 v 31 818] believes that the so-called parenteral and intestinal immunity are fundamentally the same and are produced by the same mechanism As TALIAFERRO and SABLES (*J Infect Dis* 1939 v 64 157) have pointed out *Trichinella spiralis* (and *Nippostrongylus muris*) penetrate into the epithelium of the gut and thus impregnate with their secretions and excretions the fluids of the intestinal wall so that infestations with species which do this are in reality parenteral. The existence of an intestinal immunity in the absence or lack of increase of precipitins in the blood demonstrated by BACHMAN and RODRÍGUEZ MOLINA (*Amer J Hyg* 1933 v 18 266) and confirmed by CHANDLER [this *Bulletin* 1940 v 37 216] and by GONZÁLEZ (see the present paper) is due GONZÁLEZ thinks to the fact that the above workers used an antilarval and not an antiadult antigen The view that antibodies do participate in the intestinal phase of the immunity to *Trichinella spiralis* is reinforced by the fact which has GONZÁLEZ claims been perfectly proved that the antiadult antibodies increase positively as the infestations are repeated [see also ROTH this *Bulletin* 1944 v 41 59] G Lapage

ROTH H Serodiagnosis of Trichinosis by Microscopical Testing with Living *Trichina Larvae* *Nature* 1945 June 23 758-9 1 fig

Roth (*Acta Path et Microbiol Scandinavica* 1941 v 18 160) described a method of using for the diagnosis of trichiniasis the fact that when living larvae of *Trichinella spiralis* are placed in the serum of animals immunized against this species (immune serum) granular precipitates are formed round the external openings of the larvae and in the serum [see also GONZÁLEZ above and other recent abstracts in this *Bulletin*] This method has since 1941 been used in Denmark and Sweden by Roth and in Norway by HAUGE (*Norsk Vet Tidsskr* 1944 v 56 364) BERGWALL (*Svenska Läkartidn* 1943 v 40 72) and NORUP (*ibid* 1944 v 41 2420) have also reported on it. There have been during recent years several outbreaks of trichiniasis in Norway and Sweden but none in Denmark or Finland.

The test is done as follows Larvae are obtained by artificial digestion of trichinized muscle and washed in sterile saline For each test about 100 sterile larvae are put into the hollow of a sterile thick hollow-ground slide and covered with 0.5 cc. of immune serum which has been centrifuged twice A sterile coverlip excludes all air bubbles The slides are then placed in a moist chamber (made by placing wet blotting paper in a glass dish and covering this with wire netting) and incubated at 37°C They are examined after 5 hours and again after 24 hours [contrast GONZÁLEZ in the abstract above who regards 24 hours as too short a time] If the serum contains antibodies bubble-like or finely granular precipitates are seen mostly around the anterior ends of the larvae After 24 hours the precipitates are chiefly seen in the serum The amount and form of the precipitates vary greatly and depend largely on the age and size of the infestation The reaction usually becomes positive between the 10th and the 20th day after the first appearance of symptoms but in a few instances a faint reaction was obtained before the 10th day The commonest

first symptoms are fever and oedema of the eyelids. From mild cases the antibodies seem to disappear about a year after recovery from the disease. Roth diagnosed 80 subjects in this way and could exclude trichiniasis from the differential diagnosis of 30 others in whom trichiniasis had been suspected. The test was Roth considers more sensitive and more specific than the intradermal or precipitin tests. [The author does not give details of his cases in support of this conclusion.] Similar reliable results "were obtained when the test was applied to pigs (which were positive 17 days after infestation) dogs cats silver foxes and guinea pigs. G Lepage

STUESSENGUTH Hazel & KLINE B. S. A Simple Rapid Flocculation Slide Test for Trichinosis in Man and in Swine. *Amer J Clin. Path.* 1944 Sept., v 14 No. 9 471-84 1 fig & 4 charts. [44 refs]

The authors describe a flocculation slide test (also outlined by McNAUGHT below) for the diagnosis of trichiniasis in man and in pigs which can be done in "less than ten minutes" and is they claim simple, sensitive and specific.

The test is a development of Stuessenguth's observation that an alkaline aqueous extract of powdered *Trichinella* larvae has the power of coating cholesterol crystals and of acting as a specific and sensitive antigen in a flocculation slide test. It is suggested that extracts of other injurious agents may act in a similar way and provide antigens for similar flocculation slide tests.

The materials used are essentially the same as those used for the flocculation slide test for the diagnosis of syphilis devised by KLINE (*J Lab & Clin. Med.*, 1930 v 16 186) see also *Bulletin of Hyg* 1930 v 5 87 1931 v 6 174 & 692]. The antigen used is an alkaline aqueous extract of *Trichinella* larvae. Larvae isolated by digestion from trichinized rat muscle are recovered by the modification of the Baermann apparatus devised for this purpose by HOBWATER and MEYER (*Science* 1937 Dec. 17 568). The larvae are then dried in a vacuum desiccator over sulphuric acid for 24 hours and ground up in a glass mortar to a very fine powder. This powder is then extracted with 4-8 per cent. sodium carbonate solution. From this extract an antigen emulsion is prepared by placing 0.43 cc. of distilled water in a one-ounce bottle and allowing 0.5 cc. of 1 per cent. cholesterol (Pfanztehl C.P. precipitated from alcohol for Kline tests) solution in absolute alcohol to fall drop by drop into the bottle. After rotation of the bottle for 20 seconds on a flat surface, 0.15 cc. of antigen is pipetted into it and the bottle is shaken for 1 minute. Then 1.12 cc. of 0.85 per cent. sodium chloride solution is rapidly run in and the bottle is again shaken for one minute. The emulsion thus obtained is refrigerated overnight and is then ready for use. It retains a satisfactory sensitivity and specificity for 8 weeks if it is kept tightly corked and in the refrigerator. The crystals of cholesterol should then be very small, uniform in size and completely dispersed. If they are not dispersed because the antigen had not coated them another 0.15 cc. of antigen emulsion is added and the bottle is again shaken. Any flaky material found after refrigeration overnight is removed by centrifuging.

The test is done by first heating the serum to be tested to 56°C. for 30 minutes or to 61 to 63°C. for 4 minutes and then pipetting 0.05 cc. of it into the kind of paraffin-ringed slide used for the flocculation slide test for the diagnosis of syphilis. Twelve sera can be tested at one time. One small drop of the antigen emulsion is allowed to fall into the serum from a Wright pipette or from a syringe with a 28-gauge needle. The slide is then rotated on a flat surface for 4 minutes through a circle three-quarters of an inch in diameter at the rate of 150 rotations per minute. Faster rotation reduces the sensitivity of the test. The result is then read at once through a microscope at a magnification of $\times 100$. If the reaction is negative the crystals of cholesterol coated with the antigen are completely dispersed and there is no clumping.

In flocculation tests coarse microscopically visible antigen particles require much less antigen to alter their surfaces than is required by those present in the fine dispersions of precipitation (see EAGLE, *Bulletin of Hyg* 1931 v 6 375 KLINE *J Lab & Clin Med* 1931 v 16 1202 and ZINSSER *J Immunology* 1930 v 18 483). In the precipitin test the titre is determined by using dilutions of the antigen solution and an optimal amount of undiluted serum in the flocculation test the titre is determined by using progressive dilution of the serum and an optimal amount of antigen emulsion and it is truly a measure of the antigen content of the serum. The use of the paraffin ringed slides and rotation accelerate the reaction.

Positive flocculation reactions of the type here described were obtained by the authors with the sera of 14 human subjects. In 13 of these trichiniasis was also diagnosed by clinical evidence biopsy was positive in 9 and negative in one of these 13 and on 3 of them it was not done. One subject not diagnosed clinically gave a positive flocculation test and a negative biopsy the authors suggest that this may have been a false positive.

Negative flocculation reactions were shown by 882 human subjects. Among these (a) 857 showed no clinical evidence of trichiniasis three of these 857 were infested with *Ascaris Echinococcus* and *Entamoeba histolytica* respectively and 140 gave positive flocculation reactions for syphilis no biopsies were done on these 857 subjects (b) 24 showed some clinical evidence of trichiniasis two of these gave negative biopsies on the remaining 22 biopsy was not done (c) one subject showed clinical evidence of trichiniasis but gave a negative flocculation reaction unspecified parasites had, however been found earlier in the stools of this man and presumably, these were *Trichinella* because the authors suggest that the flocculation test on him was a false negative test. Study of the sera of three human subjects which gave positive reactions showed that one was positive from the 21st to the 33rd day after infestation the second was positive on the 54th day but became negative 10 months after infestation, while the third was like the sera of pigs tested [see below] positive 10 months after infestation. [This persistence of the positive reaction in both human and pig sera and also the fact that the test is apparently specific enough to differentiate between syphilis and trichiniasis and between trichiniasis and infestation with some other intestinal parasites seem to be valuable features.]

The value of the test for the diagnosis of trichiniasis in swine was studied by testing the sera of slaughter house hogs and pigs experimentally infested by feeding them with trichinized rat muscle. Negative flocculation tests were given by the sera of 169 pigs. Of these 157 were slaughter house hogs 12 were tested before their experimental infestation these 12 gave negative flocculation reactions for longer than two weeks after infestation. Even the pig which showed the heaviest infestation from which it died in 16 days gave a negative flocculation test up to the day of its death.

Positive flocculation tests were given by the sera of eleven experimentally infested swine. The test first became positive (\pm to $++++$) in all these at about 2 to 4 weeks after infestation and remained positive for 10 months after. The highest titre in swine sera was 1/64 the lowest 1/16. The highest titre in man was 1/128 [the lowest is not stated]. The earliest peak of antibody in pig serum was found on the 23rd day and the latest on the 55th day. Eleven biopsies were done on the pigs at times varying from 16 days to 7½ months after infestation. Study of the degeneration and necrosis observed around the larvae in the pig muscle suggested that the larvae were maintaining themselves by destroying muscle cells long after they had been encapsulated.

The authors state that in the average case the flocculation reaction does not become positive until about 3 weeks after infestation. The first positive

reaction in both man and swine was obtained between the 14th and 17th days, and the 25th and 27th days. Because the average life of swine fed for the market is about one year and because the reaction may remain positive for 10 months after infestation this simple test is the authors claim a valuable means of testing swine and therefore of preventing human trichiniasis. It involves no disturbance of normal slaughter-house procedures and a number of pig sera can be tested by one man in a few minutes.

The authors give a valuable summary of the literature dealing with serological tests for the diagnoses of trichiniasis. *G Lapage.*

GOULD S. E. A New Type of Trichinoscope. *Amer J Clin. Path.* 1944 Sept. v 14 No 9 Tech. Sect 98-100 2 figs

The author has devised a ring-shaped trichinoscope. The advantages claimed for it are that it is more easily and cheaply made than other types (see, for example McNAUGHT below) and is stronger and gives a uniform compression of muscle.

It consists of two circular glass plates with a diameter of 11.5 cm. and a thickness of 3.3 mm. with ground edges. The top surface of the bottom plate may be ruled with parallel lines at intervals of 1.1 cm. These glass plates are held in flat metal rings which have an outer diameter of 13.4 cm. and an inner diameter of 10.8 cm. The outer 8 mm. of the width of each metal ring is 4 mm. thick the inner 5 mm. of the width of both of them is however counterbored to a thickness of 2 mm. The glass plates are thus held in position in a shallower (counterbored) space between the two rings. The metal rings may be chromium-plated. Compression of muscle placed between the glass plates is applied by means of two winged screws set at opposite sides of the rings which screw down upon bolts fixed to the lower metal ring. Photographs of the trichinoscope show both its separate parts and the assembled instrument.

McNAUGHT, J. B. Laboratory Procedures for the Diagnosis of Trichinosis. *Amer J Clin Path.* 1944 Sept. v 14 No 9 Tech. Sect 87-93 3 figs. [18 refs.]

DEFICIENCY DISEASES.

PLATT B. S. Tables of Representative Values of Foods commonly used in Tropical Countries. *Med Res Council Spec Rep Ser* No 253 41 pp. [Numerous refs] 1945 London H.M. Stationery Office. [91]
Summary appears also in *Bulletin of Hygiene*]

Tables of the nutritive value of foods are a basic need in any surveys of nutrition, and there is wide demand for such a publication as this for use in tropical countries. The values given here are obtained partly from an extensive survey of the literature and partly from analyses of samples collected by the Nyasaland Nutrition Survey. An attempt has been made to assess the weight to be attached to the various analyses and to arrive at representative values for a suitable range of foodstuffs. These values are considered to be sufficiently well founded for the purpose for which they have been compiled, namely the evaluation of dietary data based on records of group intake. They are not suitable for surveys by the individual method, nor for precise nutritional investigations in individual human and animal subjects.

Figures are given for 233 foodstuffs representative of the dietary commonly found in tropical countries. Values given refer to the portion usually eaten, and, where possible a figure for wastage is shown as a percentage of the food as purchased. The water content is given as accurately as possible but the

nutrient values shown may have to be adjusted to a value for water determined individually. Several more or less alternative common names are given as well as the botanical names but it seems likely that investigators may find difficulty at times in placing certain local foods.

EDISON ANN O SILBER R. H & TENNENT D W The Effect of varied Thiamine Intake on the Growth of Rats in Tropical Environment. *Amer J Physiol* 1945 Oct 1 v 144 No 5 643-51 3 figs [14 refs]

Comparable groups of rats were maintained under two environmental conditions a tropical environment of 90°F and 70 per cent humidity and a temperate one of 72°F and 50 per cent humidity. They were given a basal diet of casein dextrose hydrogenated vegetable oil salt mixture and cod liver oil. Vitamins of the B group were either added to the diet or given separately in constant adequate amounts except for thiamin the quantity of which was varied from 300 to 20 µgm daily. When placed in a tropical environment rats lost weight rapidly but after a few days resumed growth at a stable but slower rate. Food consumption in tropical conditions decreased by 30-50 per cent. the anorexia was not due to thiamin deficiency. The weight of these rats was 15-25 per cent less than that of rats given a similar diet *ad libitum* in temperate conditions but 15-25 per cent greater than that of animals in the temperate environment whose diet was restricted to amounts exactly similar to those taken by the tropical animals.

When the thiamin intake of rats kept in each environment and previously given adequate amounts of thiamin was reduced to 20 µgm thiamin daily the rate of loss of weight was less under tropical than under temperate conditions. There were indications also that polyneuritis developed more rapidly under temperate conditions.

Assays of the livers of these animals showed that the thiamin content varied with the dietary intake but was unaffected by changes of environment. The authors conclude that the thiamin requirements for the growth of rats in a tropical environment are not greater and may be less than in temperate conditions.

BIEN W N Bisulphite Binding Substances in Human Blood. *Chinese Med J* Washington 1944 Oct-Dec. v 62 No 4 358-65 [15 refs]

The blood content of bisulphite binding substances was determined in various clinical conditions. The results are not conclusive enough to warrant the assumption that whenever the B.B.S. are elevated, beriberi is present. The present experience indicates that only when renal insufficiency starvation and diabetic acidosis are not present an elevation of the B.B.S. in the blood may indicate beriberi. Conversely a lack of increase of B.B.S. in the blood does not rule out beriberi. The possible substances in the blood which combine with bisulphites are enumerated and briefly discussed.

TROWELL H C. & MUWAZI E. M. K. A Contribution to the Study of Malnutrition in Central Africa. A Syndrome of Malignant Malnutrition. *Trans Roy Soc Trop Med & Hyg* 1945 Dec. v 39 No 3 229-43 4 figs on 3 pls [38 refs]

This paper appears to have been written earlier than one published by the same authors in *Arch Dis Childhood* (this *Bulletin* 1946 v 43 143). It describes some features of a syndrome common in Uganda as observed in 200 patients at Kampala in 1943. The condition accounted for about 10 per cent

of the medical admissions of adults and about 50 per cent. of the children. Of the 144 adult cases 25 were fatal, as were 10 of the cases in children.

Rough estimates are given of the diets of the natives amongst whom the condition occurs commonly. These show that the very poor labourer's diet is seriously deficient in everything except ascorbic acid. The immigrant labourer's diet is seriously deficient in calories, protein, calcium, vitamin A and nicotinic acid, and moderately deficient in iron and thiamin. The Ganda peasant diet on to which most of the children concerned were weaned when well into their second year is moderately deficient in protein, calcium and nicotinic acid, and probably somewhat deficient in vitamin A, thiamin and riboflavin.

The soft brown hair and pallor of the facial skin that are a common early sign in children are often absent in adult cases. Children seldom show the crazy-pavement dermatosis of adults and many of them have no looseness of the bowels. Most of the features of the syndrome however are present at all ages. The clinical picture consists of a gross loss of body weight in adults or a failure to grow in children, oedema, pallor of the skin and hair, crazy-pavement dermatosis, loose stools, steatorrhoea in children, macrocytic anaemia, slight mental and neurological changes and a deficiency radiographic bowel pattern.

In the absence of sufficient details of the radiographic appearance of the normal African small intestine the authors accept only segmentation, gross irregularity, coarseness or loss of the mucosal folds as evidence of abnormality. Of 23 adults examined, 19 showed frank segmentation, five had an abnormal mucosal pattern and none was normal. 7 of the 9 children examined showed frank segmentation.

Undigested remnants of food were found in the faeces of about half the cases.

Mean figures and the range are given for blood counts on the 200 cases. The syndrome was usually accompanied by a macrocytic hypochromic anaemia, but at times the anaemia was normocytic and not infrequently orthochromic. Examination of the sternal marrow in 101 cases showed a normoblastic erythropoiesis. Plasma proteins are given for 11 adults and 3 children. The mean plasma albumin was 2.05 gm. per 100 ml. with a range of 1.10 to 3.02. The mean plasma globulin was 4.05 ranging from 1.44 to 6.77. The albumin/globulin ratio was less than 1 in all but 2 cases.

Details are given of autopsies on two male adults.

On the ordinary hospital diet progress was slow in every respect. When thiamin was given in addition to the basic diet, definite improvement was reported by many of the patients usually within 5 days. The improvement was largely subjective: no change was noted in the oedema. Giving nicotinic acid to patients taking the basic diet also led to an improvement in the condition of the majority usually within a week. This consisted of a peeling of the dermatosis: no definite effect on the diarrhoea was observed. Injections of crude liver extract led to a reticulocytosis and a satisfactory increase of red cells and haemoglobin in almost all cases.

The syndrome appears to be distinct from pellagra and from nutritional oedema: it is very resistant to treatment by improvement of the diet or by supplements of the common vitamins, and it has a high mortality. It is proposed to call it "malignant malnutrition." *H. E. Harding*

GILLMAN, J. & GILLMAN, T. Structure of the Liver in Pellagra. *Arch. Pathology* 1945 Oct., v. 40 No. 4 239-63 22 figs. [Refs. in footnotes.]

This long but interesting paper gives first a detailed account of the histology of sections of livers obtained by biopsy from 120 pellagrins on the day of their

admission to hospital. The livers are divided into four groups, each with further subdivisions that depend upon the quantity of fat present. In the first group the livers show varying amounts of fat only. Livers in the second group show cytosiderin (haemosiderin) and cytolipochrome (haemofuscin) in discrete granules in hepatic and Kupffer cells. The third group is similar to the second but iron-containing pigment is found also aggregated in large masses in cells lying either in the hepatic lobule or in portal tracts. The last group shows pigment cirrhosis. Fatty livers of the first group are the invariable finding in infants suffering from pellagra. No disturbance of iron metabolism is found at this age. Pigmented livers with or without visible fat are found in adolescents and adults.

Evidence is given that pigment is formed in the cells at a time which coincides with the disappearance of fat. The amount of pigment formed varies from case to case, the extent and the intensity of pigmentation giving an excellent indication of the degree of chronicity of the disease. The iron pigment arises within the liver cells as a result of a profound disturbance of intracellular metabolism induced by dietary imbalance. Both pigments appear to originate from mitochondria. Exacerbations of the acute stage may lead to reappearance of fat in livers which already show pigmentation from previous damage.

Repeated attacks of pellagra may cause a fatty condition to progress to frank pigmentary cirrhosis. Such cirrhosis was found in an eighth of all the pellagrins examined or in 15 per cent. of the adults. There was strong presumptive evidence that the incidence of cirrhosis might be as much as 30 per cent. Pigment cirrhosis occurred mainly under the age of 40 years and was indistinguishable clinically and pathologically from haemochromatosis. Evidence is given for the view that this condition is not a result of an inborn error of metabolism but is one of the manifestations of chronic malnutrition.

The authors believe that therapy and the assessment of its effectiveness in pellagra should be based not only on the clinical picture but more especially on the structural alteration in the liver in each case. They suggest that in pellagrins fatty change, formation of intracellular pigment with or without cirrhosis and hepatic carcinoma represent different patterns of reactivity of liver cells to acute and chronic malnutrition.

GILLMAN J. GILLMAN T. & BRENNER S. Vitamin A and Porphyrin-like Fluorescence in the Livers of Pellagrins, with special reference to the Effects of a High Carbohydrate Diet and Methionine. *South African J. Med. Sci.* 1945 Sept. v. 10 No. 3 67-88 4 figs. [36 refs.]

Fragments of liver obtained by biopsy from 60 adult and infant pellagrins were examined by fluorescence microscopy for the presence of vitamin A. There appeared to be a reciprocal relationship between the amount of fat in the liver cells and the amount of vitamin A fluorescence in the Kupffer cells: there was very little fluorescence in very fatty livers. In rather more than half the cases examined the amount of fluorescence was well below the average normal. The effects of a diet free from vitamin A but containing a high proportion of carbohydrate were erratic: the amounts of vitamin A fluorescence varied in an unpredictable manner. Administration of large quantities of vitamin A in conjunction with a full diet appeared to aggravate the disease and did not lead to as great an increase in vitamin A fluorescence as did ventriculin with a similar full diet. The fatty livers of two pellagrous children did not respond to methionine and there was afterwards a delay in the response to ventriculin.

Phrynoderma was observed in two patients whose livers showed marked vitamin A fluorescence three patients whose livers showed no fluorescence had no evidence of phrynoderma. It is concluded that phrynoderma cannot be regarded as due to vitamin A deficiency

A porphyrin like fluorescence was seen in the liver cells of a few pellagrins [More details of this are given in the following paper] *H E Harding*

GILLMAN J GILLMAN T & BRENNER S Porphyrin Fluorescence in the Livers of Pellagrins in relation to Ultra Violet Light. [Correspondence.] *Nature* 1945 Dec 8 689.

The examination, by ultra violet fluorescence microscopy of frozen sections of fragments of livers removed by biopsy from 20 African pellagrins soon after admission to hospital, showed the presence of an intense scarlet-red fluorescence in eight cases. Reasons are given for believing that this fluorescence was due to a porphyrin. Patients kept on a carbohydrate diet poor in vitamins lost this fluorescence in their livers exposure of the patients to ultra-violet light then led to a recrudescence of the fluorescence but not to aggravation of the skin lesions. Traces of porphyrins were found in the urine of only one patient.

The authors conclude that (1) Porphyrin fluorescence in the liver can occur during the acute phases of pellagra. (2) The great accumulation of iron pigment in many livers of adult African pellagrins is probably caused by the disruption of an intracellular iron porphyrin complex, such as catalase and cytochrome present normally in the liver cell. (3) Treatment with vitamin B complex is not required to resolve the porphyrin fluorescence in the livers of pellagrins while on a carbohydrate vitamin-poor diet. (4) Ultra-violet light can excite a recrudescence of the porphyrin fluorescence in the liver without causing an exacerbation of the other external manifestations of the disease. Massive quantities of porphyrins can appear in the liver cells without any detectable amounts in the urine. (5) These experiments emphasize the close inter-relationship between the reactivity of the skin to ultra violet light and the deposition of iron and the appearance of porphyrin fluorescence in the liver of African pellagrins. *H E Harding*

SPRUE.

LEISHMAN A. W. D. Thoughts on Sprue after Experience in India. *Lancet* 1945 Dec. 22, 813-15 [17 refs.]

From 1942 to 1945 the incidence of sprue amongst troops in India and the South-East Asia Command has been particularly heavy in 1944 alone 675 patients were invalided on account of this disease. The diagnosis of this syndrome presented few difficulties when it was recognized that dysentery alone was not the sole cause of diarrhoea in the tropics. On the therapeutic side there remains considerable need for improvement and even the most specific remedy liver extract acts in a manner quite unknown. Though in India there appears to be reluctance in recognizing sprue in Indians nevertheless this attitude does not appear to be wholly justifiable. What has been termed the malarial syndrome when coincident factors of malaria dysentery ankylostomiasis and malnutrition have been eliminated appears to be indistinguishable from sprue. A somewhat novel observation is that three-quarters of the [European] patients had less than 2 years tropical service when they first developed the disease that length of residence is scarcely a factor as has been previously assumed, was illustrated in one patient, who disembarked

from his ship in Bombay with fully-developed sprue after having spent 2-3 weeks in Durban on his way from Britain. In war time sprue observed a distinct seasonal incidence from March to September with a peak incidence in June during the months corresponding to the fly season (with consequent dysentery) and to the malaria transmission season.

Sixty five per cent. of cases originated in Bengal Assam and Burma but 15 per cent. came from Western India, 13 per cent. from South India and Ceylon and 5 per cent from North India one-third were soldiers living on full rations and usually in an entirely innocuous climate.

In view of the work of HOWAT which indicated that the use of sulphaguanidine in bacillary dysentery provokes steatorrhoea it is striking that a history of frank dysentery was obtained in only 9 per cent. of cases of these 4 per cent. were amoebic 3.5 per cent. bacillary and the rest clinical.

In more than half of the patients the syndrome was fully established within two months of the onset of diarrhoea but in 20 per cent. the interval was as short as 3 weeks. Loss of weight was an outstanding feature and in 95 per cent it was not less than 20 lb. Almost all the patients had changes affecting the mouth lips or tongue 20 per cent had skin changes—follicular hyperkeratosis (a sign of vitamin A deficiency) and parakeratosis (probably a vitamin B deficiency). Well marked pigmentation especially of the face was occasionally seen but never the skin changes of pellagra.

Dark-adaptation tests and slit-lamp examinations of the cornea showed no significant abnormalities in patients so tested.

Dyspepsia.—Flatulent dyspepsia was invariably present increasing towards the latter part of the day a common symptom was retrosternal burning pain.

Stools.—One important fact emerges. In 20 per cent. of cases there was no apparent increase of fat in the stools. A possible explanation is that owing to the increased bulk of the faeces due to debris and bacteria, a sample estimation does not give a true picture of fat excretion. A second anomaly concerned the pigment in the stools the presence or absence of which affords no real indication of the fat content for stools of normal colour have been found to contain great excess of fat, and *vice versa*.

Leishman reverts to a formerly widely held hypothesis that the normal stool pigment in sprue is reduced to a colourless compound and that this constitutes a classical feature of the syndrome. [A reduction product of hydrobilirubin in sprue was described by NENCI and an account of its chemistry is given by VAN DER SCHEER in *Mense's Handb der Tropenk* 1905 v. 1 20. This was investigated by the reviewer in Ceylon. A colourless extract was obtained by trituration of the freshly passed faeces in 90 per cent. alcohol and filtration. When exposed to the sunlight or shaken with air the extract changed to light yellow or brown. The same effect was produced by the addition of a drop of nitric acid. There appeared to be grounds for supposing that hydrobilirubin is present in sprue faeces but that the greater part is reduced to leucourobilin. That normally coloured bile is secreted in sprue has been ascertained at post-mortem. According to STRASBURGER, *Die Fäzes des Menschen* 1910 leucourobilin is identical with urobilinogen. See also a Report on Researches in Sprue in Ceylon 1912-1914 Cambridge University Press pp 50-51.]

More than half the cases had acid curves (by test meal) within normal limits.

The author satisfied himself that full recovery from sprue could be made in India and he supports the opinion that when once a patient has fully recovered a return to India may be permitted. There were seven fatal cases a case-mortality rate of about 1 per cent. The cases which give rise to anxiety are those which are profoundly emaciated with a striking degree of hypotension,

although there is some dehydration, hydration achieves only limited improvement and desoxycorticosterone is without effect. In cases of this type there is consistently a diminished plasma volume with low blood sodium and chloride the potassium level being normal. Plasma proteins were slightly diminished but not to the extent found in starvation cases. In the few cases in which hypochloreaemia, as well as the dehydration was treated, the response was not striking plasma transfusion had little advantage over saline. It seemed clear that no form of parenteral therapy could act as a substitute for food given by the mouth.

As regards aetiology the author considers that in many respects sprue behaves like an infection although usually sporadic it occasionally attains epidemic proportions. In 1943 in Chittagong nine separate units were affected and in some the incidence was 50 per cent. In one R.A.F. unit within 3 weeks of arrival there 10 per cent of the men had diarrhoea which rapidly developed into sprue. It was thought at the time that some tinned meat might have been a factor in causing the initial enteritis. The popular idea of "sprue houses" would suggest some infective agent but none has yet been found.

The author agrees with SROVER (1942) that interference with the absorptive process is the result of failure in the phosphorylation of fatty acids. The primary failure in sprue is lack of vitamins of the B group (well-known and [perhaps unknown] for without these phosphorylating enzymes cannot be constituted. By accepting this view however difficulties are encountered, for in sprue a history of inadequate vitamin-intake is seldom obtained. The recent knowledge of biosyntheses by intestinal bacteria. BENESCH [*Bulletin of Hygiene* 1945 v. 20 564] provided evidence that nicotinic acid is synthesized by aerobic and destroyed by anaerobic organisms within the human intestine and that in health an equilibrium must exist between those which produce and those that destroy vitamins. The infective character of sprue may now become capable of a more liberal interpretation, and be linked with the conception of sprue as a deficiency disease synthesizing organisms may be swamped by infection with non-synthesizing organisms which otherwise are not pathogenic and stagnation in the small intestine due to unaccustomed diet may provide a medium in which the latter flourish.

This hypothesis has the merit that it can be put to the test. A series of vitamin-excretion estimations in patients with sprue and in controls on a standard low vitamin diet should be made together with an investigation of the small intestine flora on the lines employed by BENESCH to determine the relative proportions of aerobes and anaerobes and their ability to synthesize nicotinic acid and other members of the B group. For this purpose samples must be collected by means of the Miller Abbott tube which, it has been found, can be used in sprue.

Philip Manson-Bahr

KEELE, K. D. & BOUND, J. P. Sprue in India. A Clinical Survey of 600 Cases. *Brit. Med. J.* 1946 Jan. 19 77-81 2 figs.

For the present purpose sprue is defined as a syndrome consisting of diarrhoea, with the passage of light-coloured stools of high fat content, sore tongue flatulent dyspepsia and emaciation. Malnutrition may indeed manifest itself as the sprue syndrome, but steatorrhoea is too variable a feature upon which to separate the two and the syndrome as defined above has been diagnosed as sprue "even in the presence of an isolated normal faecal fat."

Throughout India during the recent war period the incidence of sprue was highest in May and June it was minimal in November December and January in both 1943 and 1944. This applied whether the cases originated in the cool climate of the Assam Hills (54 per cent.) or in the hot plains of Bengal

and Bihar (23 per cent) or in the rest of India (23 per cent.) The geographical distribution of 450 cases was Assam and N Burma 54.2 per cent. Bengal and Bihar 23.1 per cent. S India and Ceylon 9.1 per cent. Bombay Presidency 8.9 per cent. NW and Central India 4.7 per cent. Within a climatic zone sprue is regional. For instance 14 per cent. of cases in the present series occurred near Imphal and the high incidence in this place continued long after the siege had been raised. Chittagong (9 per cent) on the coast at the edge of the Ganges delta produced quite a nest of cases—six from one aerodrome in two weeks. The difference in climate between these two localities illustrates how the local regional factor may supersede that of climate. The maximal incidence occurred after one or two years service in India. The earliest was in the Red Sea *en route* to India. Heat adaptation was probably not an important factor.

In a comparison of the seasonal incidence of sprue and dysentery (amoebic and bacillary) it was found that the incidence of sprue precedes that of dysentery suggesting that it is unlikely that sprue commonly follows an attack of dysentery. In 23.6 per cent of cases dysentery preceded sprue but there was no significant difference between the incidence of dysentery in the cases of sprue. In some individual cases however a close relationship is found to exist between an attack of amoebic or bacillary dysentery and the sudden passage of sprue stools. In one group of 87 cases labelled malnutrition in the Chindit Forces (in June and July 1944) were included 52 with the sprue syndrome. Analysis of the stools of 15 showed 12 with faecal fat over 30 per cent. Malaria was frequent and whilst response to sprue therapy was unsatisfactory improvement was dramatic after the development and subsequent treatment of malaria. Although the brunt of incidence of sprue falls on Anglo-Indians and Europeans it is undoubtedly true that Indian troops have developed the full syndrome during this war.

Regarding the influence of diet little information of value was forthcoming. Most of the patients developed diarrhoea under jungle conditions but many were on field service rations. A large number became ill on a diet composed of protein 95–103 gm fat 114–143 gm carbohydrate 425–435 gm with calcium 1.6–1.7 gm iron 20–25 mgm. vitamin A 1450 I U thiamin 1.2–1.8 mgm riboflavin 2.1 mgm niacin 16.3 mgm ascorbic acid 6 mgm (with supplementary tablets of 50 mgm). This diet well balanced and adequate as it appeared, was found monotonous and distasteful.

In contrast to the classical picture the type of medical history was as follows—After jungle training and contracting the customary short fevers and dysentery the soldier became involved in fighting in Burma and subsisted on the diet already detailed. The onset of diarrhoea was gradual and was usually attributed by the patient to his diet. Soon anorexia and glossitis were noted with flatulent dyspepsia and heartburn. After reporting sick he was admitted to hospital and rapidly improved but on returning to duty the diarrhoea recommenced and the typical sprue syndrome evolved. The result might be mild acute sprue with continual relapses if as so often happened he was returned to duty in India. The severe form proceeds from the onset to produce dehydration emaciation and a smooth dry tongue. Statorrhoea is obvious. Severe anaemia may develop suddenly necessitating transfusion. Though response to treatment is often satisfactory men with this type had to be evacuated from India. On an average the period between onset and evacuation was about one year in both mild and severe cases.

Post-dysenteric sprue was noted especially after amoebic dysentery in these cases the sprue syndrome was either temporary or severe and long standing.

Several instances of subacute hepatic necrosis without jaundice were observed in which there were symptoms of sprue—the latter improved as the liver diminished in size.

The clinical picture of incomplete sprue was seen in 3.6 per cent. of cases—the diagnosis noted on the finding of steatorrhoea and other signs of sprue in cases of chronic diarrhoea which had been treated as chronic dysentery. At the other extreme are cases of glossitis with minimal steatorrhoea conveniently termed "larval sprue." In this series 20 per cent. had total faecal fat of less than 30 per cent. and it is more than probable that the numbers with normal fat excretion would have been greatly reduced had it been possible to repeat the examination.

Glossitis was practically constant (96 per cent.) in this series and the longer the cases were observed the fewer were the exceptions. The tongue changes were found very variable but coincided within a day or two with diarrhoea. Glossitis responded surprisingly quickly to diet, but administration of nicotinic acid and riboflavin often seemed to accelerate improvement. Cheilitis and angular stomatitis occurred in 40 per cent. and did not respond so quickly. The typical magenta tongue of riboflavin deficiency was not seen. The appetite ranged from extreme voracity to extreme anorexia. Rash increase of diet, on the return of appetite provoked relapse. Vomiting was present in 18 per cent. particularly in cases of acute onset. Heartburn was common, and caused considerable distress—dysphagia was not marked. Dyspepsia, on the other hand, of the flatulent type was practically constant (94 per cent.) and was exacerbated by administration of fats—the gastric juice, however was normal in at least 68 per cent. Distension, a salient feature appeared early and disappeared late, being maximal in the hypogastrium. The abdominal girth altered by 1-2 in. only though the patient's sensation leads him to expect more. Barium meal examinations failed to show convincing evidence of small intestine dilatation, but one instance of megacolon was found in one who did not exhibit undue distension but made a good recovery. Diarrhoea often as acute and as painful as in dysentery with passage of 15-20 pale watery stools was a constant feature and its response to sulphaguanidine was similar to that of dysentery but the stools were devoid of exudate and there was neither pyrexia nor leucocytosis. The onset of sprue was often sudden and unexpected. Diarrhoea preceded glossitis by about six weeks in 80 per cent. of the cases—the reverse very rarely.

On admission most patients had lost 25 per cent. of their normal Indian war time body weight. The average loss ranged from 20 to 60 lb. at body weights of 130 to 195 lb.

Cramps usually in calves and thighs, were present in 25 per cent. No osteoporosis was observed. Chvostek's and Trousseau's signs were negative except in one solitary case. Response to liver nicotinic acid, calcium gluconate, salines and transfusions was satisfactory from the clinical viewpoint.

Dry skin with depilation was common, whilst scaling of parakeratotic type occurred in 27 per cent. Follicular hyperkeratosis responded quickly to treatment and cleanliness and, though it suggested a vitamin A deficiency dark adaptation tests were normal in 19 of 20 patients with one exception. Pigmentation occurred in 4 per cent. and was so extensive in one patient as to suggest haemochromatosis. The distribution did not suggest pellagra.

Hypotension below 100/70 was noted only in 8 per cent. all severe cases with dehydration and low urinary chlorides—this hypotension persists and rises slowly in response to treatment. No evidence of left or right-sided heart failure was found.

It was thought that these cases would present examples of typical deficiency states but this did not turn out to be so. In some obdurate cases of glossitis

nicotinic acid proved effective but though glossitis with angular stomatitis was common other signs of riboflavin deficiency were absent. No case showing evidence of vitamin B₁ or C deficiency was seen.

Pallor of the faeces at some period was almost constant and was due not only to the high fat content, but also to alteration of bile pigment. A pale stool may have a normal fat content a coloured stool may have a raised fat content. Microscopically fatty acid crystals fat globules and soaps may be seen but give little guide to quantitative fat excretion. Analysis of single stools showed great variability two consecutive specimens for instance showed 21 per cent. and 36 per cent. total fat content respectively. For routine examination 24-hour collection of stools well mixed, should be a minimum procedure. A further proviso is that the daily fat intake for at least the three previous days should be known. In 10 normal persons the total fat averaged 30 per cent. on a fat intake of 70 gm daily but in 20 per cent. of the cases of sprue the faecal fat was below 30 per cent. conversely high faecal fat above 50 per cent. did not indicate clinical severity. Fat splitting was excessive in the majority of 274 cases the ratio of split to unsplit fat was between 3-1 and 10-1. The high ratio might be interpreted as due either to delayed absorption or to excessive lipase action. Hyperchlorhydria or normal acid curves were present in 68 per cent. in 27 per cent. hypochlorhydria (less than 10 units HCl) was present.

Severe anaemia was uncommon even in clinically severe cases though blood crises were observed in a few. The few blood-sugar curves which were carried out showed normal fasting values with the low rise as generally described in sprue.

The object of treatment was to make the patients fit to travel and the authors have not made innovations they do however remark on the value of parenteral crude liver extract in severe cases. The response to sulphaguanidine in acute cases up to a total of 70 gm. was found to be good. Immediate prognosis for life was good. No patient in the 600 of this series died. Of 40 cases followed up for one year six have had severe relapses and the remainder less severe recurrence of symptoms none has remained quite well.

HAEMATOLOGY

EVANS R. W. Anaemia associated with the Sickle Cell Trait in British West African Natives. *Trans. Roy Soc Trop Med & Hyg* 1945 Dec. v 39 No 3 207-20 [12 refs.]

A diagnosis of sickle cell anaemia based solely on the association of anaemia with sicklaemia is unjustified, as factors other than sickling of the cells may be responsible for the anaemia of patients with the sickle cell trait. In one series of patients suffering from anaemia associated with sicklaemia the sickle cell haemolytic crises may well have been initiated by anaemias of different aetiology. Complete haematological investigations showed such underlying conditions as megaloblastic nutritional anaemia hypoplastic anaemia of undetermined origin and anaemia due to hookworm infection dietary deficiency and malaria. In unmasking the bases of these anaemias the value of bone marrow examinations has been shown repeatedly. During a sickle cell crisis the marrow shows an intense erythroblastic and leucoblastic hyperplasia with considerable increase in the number of monocytes many of which may contain engulfed red cells. The normoblasts tend to be large early eosinophilic forms

with a well patterned nucleus such as are found in haemolytic anaemias and in conditions of prolonged loss of peripheral blood. The diagnosis of a sickle cell haemolytic crisis will therefore be suggested by an anaemia with leucocytosis jaundice and a hyperplastic bone marrow which shows no abnormal cells occurring in a patient whose red cells have been shown to exhibit sickling *in vitro*. It is then confirmed by the demonstration of sickle cells *in vivo*.

In a second series of patients the sickle cell crises appeared to have been precipitated by other more urgent diseases or acute toxic conditions such as tropical myositis and blackwater fever meningitis and Addison's suprarenal disease. In these the spleen at autopsy presented as a small hard, nodular grey organ. Cut sections showed thickened trabeculae and yellowish-brown nodules scattered throughout the pulp—the result of organization of haemorrhagic areas. The pulp itself had been transformed into a reticular mass packed with sickle cells. These extensive degenerative changes may be taken as evidence of frequent sickle cell crises that had occurred in the past. Lesions found in other organs are fundamentally similar to those which have been described in the spleen namely tissue destruction by haemorrhage and thrombosis followed by necrosis. These observations suggest that the chief feature of the condition is not the anaemia but the liability to thrombosis which occurs during a sickle cell crisis. The term "sickle cell disease" would therefore appear to be preferable to "sickle cell anaemia". *F. Margatroyd.*

ALTMAN A. The Sickle-Cell Trait in the South African Bantu. *South African Med J* 1945 Dec. 8 v 19 No 23 457 20 refs.]

"Of 403 blood specimens of South African Bantus only one showed the sickle-cell trait in a moist sealed preparation after 24 hours incubation at 37°C. The sickle-cell trait which is very common in the West African and American negro is rare in the South African Bantu."

WOOFER A. C. DICK, W. S. & BIERING W. L. Sickle Cell Anemia in White Patients with Ulcers of the Ankles. Report of Two Cases. *Arch. Intern. Med* 1945 Oct. v 76 No 4 230-33 4 figs. [Refs. in footnotes.]

Sickle cell anaemia is almost exclusively a disease of the Negro race, although several instances of the disease have been reported in patients thought to be without Negro ancestors. Ulcers on the legs or ankles unilateral or bilateral, have appeared spontaneously or after mild trauma in Negro patients suffering from this condition healing is prolonged and followed by scarring. Hitherto however all available case histories of the disease in the white race have failed to mention or have noted the absence of ulcerations or scars about the ankle joints.

The present report describes two patients from one family suffering from sickle cell anaemia, with ulcers of the ankles and limitation of motion about the ankle joints. The first patient a 20-year-old white youth was admitted to hospital complaining of ulcers on both ankles the ulcers having appeared when he was 13 years of age after an attack of dermatitis venenata (ivy poisoning) and having persisted until the time of his admission to hospital. The second patient the 14-year-old sister of the first, had a small ulcer on the right ankle which had existed for approximately three weeks. Both patients were anaemic and 15 and 18 per cent respectively of their erythrocytes showed sickling. Other physical and laboratory findings were confirmatory of sickle cell anaemia the Wassermann and Kahn reactions were negative. The family history revealed that the paternal grandmother had been pale and suffered from ulcers of the ankles, and that the father and an uncle had both been pale and had had scarring and fixation of both ankle joints. The parents

of the grandmother the first reported member of the family with the disease were known by a local historian to have been normal and of the white race. [The remainder of the ancestry is not recorded it may have contained a negroid element.]

TOMLINSON W J A Study of the Circulation of the Spleen in Sicklaemia and Sickle Cell Anemia. *Amer J Path* 1945 Sept v 21 No 5 877-87
6 figs on 8 pls [12 refs]

Histological changes in the spleen in sicklaemia have been stated to be congenital in origin but in a large number of cases no congenital vascular abnormalities have been found. It is possible therefore that the splenic picture may result from the sickle cells

In the normal spleen follicular capillaries arise from the central arteries pass through the substance of the follicles and terminate just beyond the marginal zone by numerous small openings into the red pulp always at considerable distances from the nearest venous sinuses. Follicular capillaries frequently unite by short branches. In some instances the endings are distended presenting ampullae with restriction of erythrocytes into the pulp the escape of plasma through the endothelial walls. In others large openings between the endothelial cells allow the passage of erythrocytes into the pulp cords and thence through stomata into the venous sinuses. Capillaries of the marginal zone arise from branches of the follicular capillaries passing into the red pulp where they branch the small branches terminating in the pulp zone of the follicle in the pulp spaces. The tips of these capillaries are usually distended into thin walled ampullae with narrow clefts leading into the pulp spaces. Capillaries of the pulp cords are branches of the capillaries of the marginal zone and terminate in the pulp spaces with or without ampullae and in some cases perhaps open directly into the venous sinuses. It seems however that the circulation of blood in the spleen is open with the pulp spaces constituting the connexions between the arterial and venous channels.

Routine autopsy sections of spleen from 150 cases of sicklaemia and 24 cases of sickle cell anaemia showed no evidence of congenital or other abnormalities of the arteries or arterial capillaries. In most cases pooling in the marginal zone was marked. The sickled erythrocytes were compressed and packed, usually in a circular lamellated fashion with obvious overlapping in the dilated pulp spaces. The venous sinuses were generally collapsed.

In preparations perfused through the arteries the erythrocytes were washed out of the arteries arterial capillaries and the venous sinuses but were present in the pulp cords especially in the marginal zones which obviously represented the pools. There was no evidence of abnormal dilatation congenital defects or of direct emptying into the venous sinuses. It is impossible therefore to explain the pooling in the marginal zones by changes in these arterial capillaries.

Venous perfusion produced filling of the small venous sinuses with erythrocytes and emptying of the arterial channels. The pulp cords contained erythrocytes and the pools were accounted for by these distended pulp cords no evidence of reverse flow of erythrocytes from the pulp cords into the arterial capillaries was present. It appeared that the perfused fluid carried the erythrocytes from the larger veins back into the smaller venous sinuses then the fluid escaped from the venous sinuses into the pulp spaces through the stomata and then into the arterial capillary endings in the pulp cords washing out the erythrocytes originally present in these capillaries. No abnormalities were demonstrated in the arterial capillary terminations or ampullae and no pools were produced in the venous sinuses despite the reversal of the circulation.

daily for two to three weeks for the most part although reticulocytosis was observed after even a single dose by mouth, larger doses of about 100 mgm. were given daily for 19 to 38 days. Diets were regulated carefully so that the source of extrinsic factor would be minimal.

Thirteen of the patients showed a positive haematological response consisting of reticulocytosis and subsequent rise of erythrocytes haemoglobin and leucocytes and in cases where treatment was continued the regeneration progressed to normal levels the responses to treatment paralleling those afforded by potent liver extract. In addition a feeling of subjective improvement occurred between the third and fifth days of treatment before the day of the initial reticulocyte response the symptoms were also improved diarrhoea disappeared, glossitis cleared, while the paraesthesiae of combined system disease were partially relieved. Further studies have shown that synthetic folic acid is effective in treatment of the macrocytic anaemia of sprue pellagra, and pregnancy it had no effect on anaemia due to iron deficiency on several types of anaemia associated with hypoplastic bone marrow and on "myelophthisic" anaemia due to aleukaemic myelogenous leukaemia.

VENOMS AND ANTIVENENES

FINLAYSON, M. H. & HOLLOW, K. The Treatment of Spider Bite in South Africa by Specific Antisera. *South African Med J* 1945 Nov 24 v 19 No. 22, 431-3.

The chief cause of venomous spider bite knopie bite in South Africa is the *Lutrodictus* either *L. indistinctus* or *L. geometricus*. Antivenenes against the former prepared from goats have been found effective in bites by the latter also. R. H. V. SMITHERS thinks that *L. indistinctus* is a colour variety of *L. tredecimguttatus* (of Southern Europe) and both *L. indistinctus* and *L. mactans* may be but variants of *L. tredecimguttatus*.

The authors have tested in mice the action of an antivenene against *L. mactans* the Black Widow spider obtained from the Argentine first against *L. indistinctus* venom and they found that 1 cc. of anti-*mactans* serum would protect the mice against 1,200 m.l.d. of the *indistinctus* venom (0.25 cc. of 1 in 60 dilution of the antiserum gave complete protection against 5 m.l.d. of the *indistinctus* venom). Next, the protective action of the same antivenene, injected intravenously in a dose of 0.2 cc. of a 1:5 dilution was tested when given 25 hours after intramuscular injection of *indistinctus* venom. All the mice survived, but two controls died in 28 and 32 hours respectively. Lastly protection against the bite of *L. indistinctus* was tested, 0.25 cc. of 1:20 dilution of the anti-*mactans* serum being injected immediately after the bite. All the mice lived, whereas a control died in 17 minutes. Whether the action is reciprocal i.e. whether *L. indistinctus* antivenene will protect against the effects of *L. mactans* bite has yet to be proved and until this is done it cannot be affirmed that the venoms of *L. indistinctus* and *L. mactans* are identical.

BELL J E Jr & BOONE J A Neostigmine Methylsulfate an apparent Specific for Arachnidism (Black Widow Spider Bite) *J Amer Med A* 1945 Dec 8 v 129 No 15 1016-17

- 1 In a typical case of arachnidism the symptoms failed to respond to calcium gluconate and sedatives for a period of five and one half hours
- 2 Dramatic and complete relief of muscle spasm and pain followed within one hour the intramuscular injection of 2 cc of 1 2 000 neostigmine methyl sulfate with 1/150 grain of atropine sulfate
- 3 This single case is presented in the hope that this apparently specific therapy will be tried in other cases without delay

DERMATOLOGY AND FUNGUS DISEASES.

WOLFE W D Diseases of the Skin among the Natives of Northeast New Guinea. *Arch Dermat & Syph* 1945 Oct v 52 No 4 247-8.

- 1 The dermatologic abnormalities in a group of 1 047 natives of north east New Guinea are tabulated and discussed briefly
- 2 The most frequently encountered cutaneous diseases were scabies ulcers and tinea these comprised 80 per cent of all diseases of the skin noted.
- 3 With the exception of yaws tinea imbricata filariasis and keratoma plantare sulcatum the type of cutaneous disease found among the natives differs little from that seen in the United States

MARPLE C D Progressive (Disseminated) Coccidioidomycosis Report of a Case. *Ann Intern Med* 1945 Aug v 23 No 2 240-49

HEAT STROKE AND ALLIED CONDITIONS.

SAPHIR W Chronic Hypochloremia simulating Psychoneurosis *J Amer Med Ass* 1945 Oct 13 v 129 No. 7 510-12

Ten cases are described with ill-defined intestinal and nervous symptoms resembling those of psychoneurosis. The blood in all ten cases was found to be deficient in chloride i.e. it contained less than 400 mgm per 100 cc. (63-4 m eq/L). The patients rapidly improved when given a regular diet with vitamin supplements and extra salt and the blood chlorides rose to the normal level. The author considers that all these men were suffering from chronic hypochloremia [although some of the improvement may well have been due to the vitamin supplements and rest]. The patients had been in the tropics for periods varying from 3 weeks to nearly 31 months [it is not stated whether they had lost weight in this time]. The author suggests that these men had not taken enough salt to prevent a gradually increasing chloride deficit though they had taken enough to prevent heat exhaustion consequent upon a sudden call on body salt and he draws attention to the possibility that chronic hypochloremia may be missed if it is not specifically looked for.

H S S Ladd.

macules and vesicles on the trunk and limbs and a few similar lesions on the external genital organs. His temperature was about 102°-103°F for a few days but soon subsided, and he recovered in rather over one week.

The authors regard the lesions of the mucous membranes as the most important part of the disease causing the fever and the severe local discomfort.

GRING, E. D. W. On Tropical Eosinophilia associated with Pulmonary Signs (Loeffler's Syndrome) *J Trop Med & Hyg* 1945 Dec.-1946 Jan. v 48 No. 6 149-51 27 refs

HAWKING F. The Choice of Sulphonamides. *Practitioner* 1946 Jan. v 156 No. 931 72-3 [Summary appears also in *Bulletin of Hygiene*.]

In this short note Hawking includes a table which, because it summarizes so clearly the sulphonamides suitable for the treatment of certain diseases will be valuable to readers of this *Bulletin*. It is a condensation of the information contained in the Medical Research Council War Memorandum on the Medical Use of the Sulphonamides (see this *Bulletin* 1945 v 42, 1052)

Table showing which sulphonamide to use in different conditions

Condition	Sulphonamide
Haemolytic streptococcal infections (moderately severe)	Sulphamylamide.
Haemolytic streptococcal infections (severe)	Sulphathiazole sulphadiazine or sulphamerazine.
Otitis media	
Meningococcal meningitis	
Purulent meningitis	
Pneumonia	
Staphylococcal infections (if penicillin is not available)	
Chancroid	
Lymphogranuloma inguinale	
Peritonitis (for insertion after operation)	
Gonorrhoea (if penicillin is not available)	
Urinary infections	Sulphathiazole or sulphamerazine.
Wounds and burns (local applications)	Sulphathiazole, sulphamylamide or mixture of the two
Bacillary dysentery	Succinylsulphathiazole sulphaguanidine or sulphadiazine
Prophylaxis against meningococcal infections or rheumatic fever	Sulphadiazine sulphamerazine or sulphamylamide.

DAVALOS A. The Rarity of Stones in the Urinary Tract in the Wet Tropics
J Urology 1945 Aug v 54 No 2, 182-4 [16 refs]

The observations recorded in this paper were made in some of the tropical regions of Ecuador South America. In certain areas of that country particularly on the west coast and in the south, urinary lithiasis is of very rare occurrence during a year of urological practice in the southern part of Ecuador the author did not see a single case among 60 000 persons examined.

The diet of the people of tropical Ecuador is poorly balanced and deficient in protein and vitamins especially vitamin A the large quantity of bananas eaten produces high acidity of the urine. In northern Peru where urinary lithiasis is common the diet is similar but the climate there is warm and dry throughout the year while in Ecuador it is hot and humid.

The average pH of the urine of 500 patients was 5.0 cultures of their urine were all negative for the common urea splitting organisms (*Proteus vulgaris* and others).

The author concludes that the rarity of urinary lithiasis in certain parts of Ecuador is attributable to the fact that the profuse perspiration caused by the climate reduces the eliminatory strain on the kidneys and the low urinary pH by inhibiting the growth of urea splitting organisms prevents the precipitation of phosphates and carbonates in the urinary tract. The rare cases of lithiasis found are due to uric acid or cystine.

LEITNER A J. Le cancer en Côte française des Somalis [Cancer in French Somaliland.] *Bull Soc Path Exot* 1945 v 38 Nos 7/8 235-41

The author gives a tabular list of malignant growths observed radioscopically and at post mortem examination in natives of French Somaliland, during the years 1939-43. The total number was 24 and included primary cancer of the liver (8) cancer of the pancreas (1) cancer of the rectum (1) cancer of the stomach (2) cancer of the oesophagus (1) cancer of the tongue (3) cancer of the breast (1) epithelioma of the ear nose jaw skin of the shoulder and skin of the abdomen one each a mixed tumour of the parotid and a connective tissue tumour of the thigh. Short notes of four cases of primary cancer of the liver are given and a few cases of various malignant growths in non-natives are mentioned.

GENERAL PROTOZOOLOGY

NERY GUIMARÃES F. Toxoplasmose humana. Meningoencefalomielite toxoplasmica. ocorrência em adulto e em recém-nascido [Human Toxoplasmosis. Toxoplasmic Meningoencephalomyelitis in an Adult and an Infant.] *Mem Inst Oswaldo Cruz* 1943 June v 38 No 3 257-320 2 pls (1 coloured) 1 map 28 figs & 2 graphs [65 refs] English summary

This is a long paper largely taken up with a historical summary of our knowledge of toxoplasmosis up to 1942. It is based on two cases seen in Brazil the one in a young man 18 years of age and the other in an infant 14 months old. Both cases were fatal and it was possible in the case of the adult to carry out a detailed histopathological study. This revealed a meningoencephalomyelitis characterized by extensive inflammatory areas with or without necrosis in the white and grey matter of the brain. Scattered through the tissues were miliary and submiliary granulomata usually situated in relation

to blood vessels. Inflammatory areas were seen in the myocardium while necrotic foci occurred in the liver and hypophysis. Typical parasites were seen in smears and in sections. They were intracellular in pseudocysts or free.

The disease in the infant was characterized by hydrocephalus with areas of intracerebral calcification, associated with tremors and convulsions. Diagnosis was established by the infection produced in animals by inoculation of cerebrospinal fluid.

The paper is illustrated by a number of microphotographs and a coloured plate showing the character of the parasite isolated. C. M. Wenyon.

BRUG S. L. & Vos J. J. T. *Toxoplasmosis hominis*. Reprinted from *Nederl Tijdschr v Geneesk.* 1942, Nov 28 v 86 No. 48 2956-63 47 figs. on 1 pl English summary

Review of the most recent literature on human toxoplasmosis. Further anatomical and parasitological details on the case observed in Groningen. In this case the sections of the brain contain parasites which were obviously multiplying by schizogony.

I. WATSON J. M. The Identity of the Ciliate *Balantidium minimum* an Alleged Parasite of Man. *Trans. Roy Soc Trop Med. & Hyg.* 1945 Oct. v 39 No 2, 151-60 4 figs. [20 refs.]

II. — Observations on the Coprophilic Habits of a Ciliate *Balantiothornus minimum* Schewiakoff. *Ibid* 161-5. [12 refs.]

i. In the first paper the author reviews the records of the discovery of *Balantidium minimum* in human faeces since SCHAUDINER first described it as a human parasite in 1899. Several writers have held that the ciliate was probably not a parasite, but a coprozoic organism which is liable to contaminate stools and that its presence has led to erroneous conclusions regarding its parasitism. The author has made a careful study of the various descriptions of the ciliate and has come to the conclusion that it is *Balantiothornus minimum* Schewiakoff, a free-living ciliate which, under certain conditions may live and multiply enormously in human faeces after they have left the body.

ii. In the second paper are given the results of an investigation into the factors which favour or inhibit the development of *Balantiothornus minimum* in human faeces. In normal stools active multiplication may occur leading to fantastic abundance of the ciliates. In abnormal stools from various sources whether loose, diarrhoeic or dysenteric, there was usually not only a failure to develop but rapid extinction occurred. The reasons for this were found to be the presence of urine, bile salts or traces of drugs and conditions of high osmotic pressure. It was determined by experiments on mice that cysts of the ciliate were unable to survive passage through the intestine. Faeces of mice fed on cysts when emulsified in water failed to yield cultures of the ciliate which, however developed vigorously when inoculated directly into such faecal emulsions. *Balantiothornus minimum* is a soil protozoan and as such is capable of living in an amoeboid form in mere surface films of water and is capable of surviving a considerable degree of drying in the unencysted state. These qualities enable it to live and survive in the viscous semi-solid material of a stool in which any ordinary ciliate would rapidly succumb. This does not mean that an organism of this type is capable of living in the human intestine. In fact, it has never been proved that any free-living protozoan can enter the intestine of a warm-blooded animal in the encysted stage and emerge from the cyst to survive or multiply in some part of the intestine. In the supposed

infections with *Balantidium minutum* it seems clear that the stools after being passed became contaminated with airborne cysts or water-borne free-living forms of *Balantophorus minutus*

GENERAL ENTOMOLOGY

BATES M Observations on Climate and Seasonal Distribution of Mosquitoes in Eastern Colombia. *J Animal Ecology* 1945 May v 14 No 1 17-25
1 pl. & 3 figs [13 refs]

This area of Eastern Colombia (S America) has a remarkably uniform climate with only 2.8°C difference between the mean temperature of the hottest month (February 27.8°C) and of the coolest (July 25.0°C). There is a greater variability in rainfall though even in the driest month (February) there is usually more than 3 in (87 mm) of rain. May is the wettest month with 28 in. (690 mm.) the annual precipitation is 180 in. (4 645 mm). Even in the driest month the noon relative humidity does not fall below 80 per cent.

Most attention in this investigation was paid to *Haemagogus capricornis*, a probably important vector of jungle yellow fever but other species of mosquitoes were also studied. Diurnal captures were made by men standing in various locations and catching all mosquitoes that came to bite. Nocturnal species were caught in a stable trap baited with a donkey.

Haemagogus capricornis was by far the commonest diurnal mosquito accounting for nearly 80 per cent of those captured. *Anopheles rangeli* comprised over 50 per cent. of the nocturnal catch.

Most species were scarcest in March i.e. at the end of the dry season. They then reached a maximum about June and fluctuated for the remainder of the year. The reasons for these fluctuations are discussed.

ROUBAUD E. & COLAS-BELCOUR J Influence de la salure des eaux sur le développement de l'*Aedes aegypti*. [Influence of Salinity of Water on the Development of *Aedes aegypti*] *Bull Soc Path Exot* 1945 v 38 Nos. 5/6 136-45 [12 refs]

In a large series of experiments gravid female *Aedes aegypti* were given water of five different salinities ranging from tap water (containing only 0.146 gm. NaCl per litre) to full strength sea water in which to oviposit. The 17 940 eggs laid in all these experiments were distributed as follows: tap water 28.9 per cent of the total eggs; tap water plus 31 per cent sea water 28 per cent; tap water plus 42.6 per cent sea water 22 per cent; tap water plus 62 per cent sea water 17.8 per cent; sea water 3.1 per cent.

Observations on the activities of the insects revealed that non-gravid and gravid females alike (and also males) were equally attracted to all these five samples of water. Egg laying is soon discontinued in the strong saline solutions the saline concentrations being apparently detected by the posterior extremity of the abdomen which comes into contact with the water-surface during oviposition.

KENNEY M. Experimental Intestinal Myiasis in Man. *Proc. Soc. Exper Biol & Med* 1945 Nov., v 60 No. 2, 235-7

"From 60 volunteers fed with living maggots of *Musca domestica* Calliphora, and Sarcophaga under conditions to avoid their destruction in the stomach, only 10 failed to have symptoms of gastro-intestinal disturbance.

In 50 cases men had nausea, vomiting, intestinal cramps and diarrhea together or as separate symptoms but all symptoms disappeared within 48 hours following the elimination of the larvae of which only a few were found alive in the vomitus and stools.

"These findings seem to indicate that though temporary gastro-intestinal distress may follow the ingestion of such dipterous larvae as *Musca domestica* Calliphora and Sarcophaga they do not produce a true intestinal myiasis in man.

LABORATORY METHODS.

HAY S. Despatch of Material for Histological Examination. *Edinburgh Med J* 1945 Nov v 52, No. 11 426-9

Correct treatment of tissue before posting it to a laboratory for histological examination is specially important in the case of biopsy tissue. The three main injunctions are (1) put it at once into fixative without previous washing in water (2) do not cut into it (3) send it without delay. The best general fixative is a mixture of formalin with 9 parts of tap water.

Biopsy material may be (1) large such as a breast with the glands (2) medium-sized, such as an encapsulated tumour and (3) small such as uterine curettings. In the case of large material if the surgeon wishes to see the type of lesion he should not gash it irregularly but should make one planned cut in the most suitable axis not quite through the whole but so as to leave a hinge so that the whole can be closed up again. Medium-sized material should be at least $\frac{1}{2}$ to $\frac{3}{4}$ in. thick and should be cut in the best direction to include all tissues affected and healthy including an advancing margin and a diagnostic part. If the specimen is too large for despatch in fluid, it may be wrapped in formalin-soaked cloth covered by "Cellophane" or gutta-percha tissue. Small material such as uterine curettings should be put into a small linen bag (not a gauze bag) in the fixative to avoid any loss.

In all cases freshly removed tissue should never be placed on dry gauze as this has a powerful desiccating capillary effect.

Bottles should be nearly full as a large volume of air tends to injure the specimens. They should, of course be securely sealed and packed, and notes should be enclosed. J F CORSON

[No. 5

SUMMARY OF RECENT ABSTRACTS.*

IV TRYPANOSOMIASIS

AFRICAN TRYPANOSOMIASIS.

Epidemiology

MACKICHAN (p 13) reports an outbreak of human sleeping sickness in Uganda in which during the period 1940-1943 there were 2,432 known cases and 274 deaths. The outbreak was declining when the author wrote the paper. Clinical and experimental evidence indicated that the trypanosome concerned was *T. rhodesiense* and the author states that this organism has not apparently been isolated previously in Uganda [but DUKE (p 13) writes that it was found several years ago]. One of several volunteers was infected with trypanosomes which were passed through rats from wild-caught *Glossina pallidipes*. The outbreak was probably due to the introduction of infection by labourers brought from Tanganyika Territory.

CECCALDI (p 710) reports on sleeping sickness in French Equatorial Africa.

Actiology

VAN HOOFF *et al* (p 96) quote the arguments which support the view that *T. gambiense*, *T. rhodesiense* and *T. brucei* are biological races of a single species rather than independent species. To distinguish between them these authors have studied the forms present in the salivary glands of infected tsetse flies and have concluded that the distribution, relative numbers and dimensions of the various developmental forms in the salivary glands provide a ready means of differentiation between *T. gambiense* on the one hand and *T. rhodesiense* and *T. brucei* (which are indistinguishable) on the other. These differences are set out in tabular form for which the original abstract should be consulted. In comment, HOARE remarks that since the differences between the two subgroups are purely relative, the three species of polymorphic trypanosomes must still be regarded as morphologically identical and he notes that certain facts mentioned by the authors appear to be contradictory.

STEFANOPOULO and ÉTÉVE (p 258) have shown that a strain of *T. gambiense* previously reported by ROUBAUD and PROVOST to have neurotropic properties

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 42. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

for mice does in fact, produce meningo-encephalo-myelitis in these animals. It had previously been thought that mice showed blood infection only.

RODHAIN and VAN DEN BERGHE (p. 872) have succeeded in infecting chick embryos with certain spirochaetes, leishmania and trypanosomes. Most of the pathogenic organisms grew in the embryos but all the non-pathogenic organisms failed to do so.

TRANSMISSION.

BAX (p. 702) reports on the work of the Tsetse Research Department (Tanganyika Territory) since February 1944. The items of work done are too numerous to be recapitulated here, and the original abstract should be consulted for details. Mention may however be made of an attempt to oust *G. swynnertonii* by introducing into its habitat large numbers of pupae of *G. morsitans*. The latter fly soon outnumbered the former and some hybrids were caught but it is too soon to know if the experiment was successful.

POTTS (p. 88) reports an attempt made at cross-breeding between *G. morsitans* and *G. swynnertonii*. A few hybrids were obtained, and some of these hybrids (females) were fertile after insemination by *G. morsitans* or *G. swynnertonii*. Further matings did not produce offspring. Cross-mating seems to occur less readily than mating within the species [but see VANDERPLANK, below] but the evidence suggests that the introduction of large numbers of pupae of an alien species into country where the indigenous species is not plentiful may lead to cross-mating and the production of relatively few and infertile offspring. This is a possible method of tsetse control. VANDERPLANK (p. 99) gives a table of the cross-mating which he has effected between *G. morsitans* and *G. swynnertonii*. Insemination occurred as readily in the cross-matings as with the same species where no choice was offered, but the cross-matings produced far fewer pupae. The author brings out the point that a few hours after a female is inseminated "she is no longer attractive to males and will not permit further coitus."

JACKSON (p. 186) has continued his observations on a *G. morsitans* population and has confirmed his finding that dispersal consists largely of movement within ambits governed by vegetational boundaries which are rarely more than half a mile in radius. It appears that a catch of one "old" male fly per 10 000 yards represents a population of some $7\frac{1}{2}$ "old" males per square mile and perhaps twice as many females. The author discusses the factors which bear on these conclusions and which must be taken into account in computing results.

CHORLEY (p. 88) has found *G. palpalis fuscipes* breeding as far as 12 miles from water in dense humid forest broken up by elephant tracks. He thinks that the general limitation of the fly to waterside areas is determined, not by food supply (which exists elsewhere) but by climatic conditions of shade and humidity.

In the Uganda outbreak MACKICHAN (p. 13) found three species of *Glossina* — *G. pallidipes* (the chief if not the only vector in the area) *G. palpalis fuscipes* (which breeds in evergreen forest as far as 10 miles from water) and *G. brevipalpis*.

WILLIAMS (p. 14) in one small experiment in Portuguese East Africa found that *G. pallidipes* was most active in the evening and early morning. BURTT (p. 888) shows that *G. pallidipes* which have hypertrophied salivary glands appear to be particularly suited to the development of trypanosomes especially *T. brucei*.

JACKSON and VANDERPLANK (p. 187) have measured the diameters of red blood cells of about 40 species of East African mammals. There is considerable difference between species but closely related species have cells of about

the same size. The work was done in relation to the animals on which tsetse flies feed.

POTTS and VANDERPLANK (p 869) give their reasons for the opinion that contact insecticides (pyrethrum and DDT) are absorbed through the pulvilli of tsetse.

GASCHEN (p 453) has written a monograph on the tsetse flies of French West Africa.

Clinical Findings

In a description of sleeping sickness as it is seen in Tanganyika Territory FAIRBAIRN (p 452) makes the point that this infection (by *T. rhodesiense*) can always be diagnosed by blood examination that gland puncture is unnecessary but that in some advanced cases diagnosis can be made more quickly by lumbar puncture. Prognosis depends greatly on the protein content of the cerebrospinal fluid and can be estimated from observations made over a period of some months. Treatment with Suramin (Bayer 205) need not be stopped on account of albuminuria but vision should be tested before each dose of tryparsamide. In relapses repeated courses of tryparsamide should be avoided because of the danger of making the trypanosomes arsenic fast and because of the risk of producing optic atrophy. Monthly doses of Suramin may be given to keep the blood free from trypanosomes. The author argues against the use of Suramin as a prophylactic since there is a real danger of cryptic infection it is preferable for the individual to get a definite attack which can easily be diagnosed and cured.

A case of Gambian sleeping sickness in a British soldier who had served in Nigeria some years before is reported by GRANT *et al* (p 187). The diagnosis was not made until 2½ years after the probable time when the infection was contracted. This case illustrates the difficulty of diagnosis sometimes experienced in this infection and points to the importance of keeping in mind the possibility of sleeping sickness in returned soldiers. Referring to the paper by Grant *et al* above and to the diagnostic methods that had been used by the various medical men who had examined the patient HARDING and HAWKING (p 188) show that the well-known procedure of gland puncture might have been used with advantage and that blood culture is a simple and practical method which may give positive results when other tests are negative.

FAIN (p 14) found trypanosomes in material from sternal puncture in 11 of 20 patients with clinically advanced disease but in whom blood and gland juice (except in one instance) were negative. This method of examination is therefore useful.

SIEYRO NIETO (p 15) has made investigations on the blood picture the coagulation time the serum calcium and on various tests with the cerebrospinal fluid in trypanosomiasis as it was seen in Fernando Po. For the last he thinks the cell count more useful than the total protein figure but there may be an abnormal colloidal gold reaction in the absence of abnormal cell count or total protein and this may be the only sign of involvement of the central nervous system.

VAN GOIDSENHOVEN and SCHOENAERS (p 791) describe the preparation of an antigen suitable for the complement fixation test in trypanosomiasis.

RODHAIN and VAN GOIDSENHOVEN (p 869) have shown that the complement fixation test (in which an antigen prepared from *T. equiperdum* is used) tends to remain positive in man and in animals for some years after clinical cure. A positive test is not an indication for the continuation of treatment.

Treatment

FOWLER (p 541) has treated 42 cases of Gambian sleeping sickness with tryparsamide administered by intravenous drip the dose being 2 gm. daily

(in 2 pints of double-distilled water which take 8 hours to give) for 6-8 days with an interval of one day in the middle of the course. This treatment causes high fever and exhausts the patients. It may have been partly responsible for death in the seven subjects who died. Nevertheless in spite of the fact that there was evidence of involvement of the central nervous system in most of the patients the immediate results were good in those who survived and in patients observed for several months the improvement was maintained.

EAGLE (p. 354) reports that γ -(p-arsenosphenyl)-butyric acid has been tried in human sleeping sickness in West Africa, and that the results in early cases are satisfactory, cure being achieved within two weeks by daily injections of about 0.4 mgm. per kgm. body weight. It is ineffective in late cases and may cause toxic encephalitis in such patients.

KING (p. 971) discusses the chemical structure of arsenicals and drug resistance of trypanosomes. The paper is highly technical, and details should be sought in the original abstract.

HAWKING (p. 971) has found that at 37°C living trypanosomes absorb a large amount of stilbamidine but that dead trypanosomes do not absorb it in any appreciable amount. Evidence was obtained that trypanosomes in the blood of animals absorb the drug *in vivo* when it is injected into the animals. SAUNDERS *et al.* (p. 354) have followed up a number of patients with Gambian sleeping sickness treated with pentamidine. The results suggest that those whose cerebrospinal fluid contains less than 30 cells per cmm. are usually cured but that in those with more than 30 there is usually relapse. In very advanced cases the drug is useless.

Control

In a paper on recent progress in the control of sleeping sickness in Nigeria LESTER (p. 789) makes the point that the disease assumes different forms—mild, toxic or nervous—and that the mild form is the most common. At the height of the epidemic some years ago teams were formed to give mass treatment, but the author thinks that where the incidence of the disease is reduced to about 1 per cent. the permanent treatment centres now established will be in a position to detect any outbreak and to deal with it. Great success has attended the work of the mass treatment teams. River clearing has been successful in eliminating the riverine tsetse from large areas and the Anchau corridor of 490 square miles is now free from fly.

In the report on the medical services of Nigeria for 1943 (p. 790) it is stated that there was no evidence of any general increase of sleeping sickness in that year. At the permanent treatment centres not only sleeping sickness but other diseases also are dealt with.

HUVER and BLOSS (p. 969) state that sleeping sickness has never been eliminated from part of the Sudan which adjoins French territory. They have attempted control by instituting a modification of SYMES's block method, to deal with *G. palpalis fuscipes* the only vector. This has been very successful. BLOSS (p. 969) describes an outbreak of sleeping sickness near Mendi in the Sudan, which was controlled by the block method and by the creation of rod clearings along the streams haunted by *G. palpalis*. Each method possesses its own advantages. He found that the disease could establish itself even where the fly density was low and contends therefore that fly control must be thorough. The infection was of the Gambian type.

TRYPANOSOMIASIS OF ANIMALS.

General

BROWAETS (p. 189) has infected mice with single trypanosomes from a strain of *T. brucei* maintained in Paris. The incubation period was usually

longer than when several trypanosomes were injected, but the duration of the disease was not apparently related to the dose

FIENNES *et al* (p 791) describe the course and pathology of *T. congolense* disease of cattle. VANDERPLANK (p 703) has succeeded in infecting *G. longi pennis* and *G. fuscipennis* with *T. congolense* and has found one female *G. austeni* infected in nature with the same trypanosome

KUBES (p 454) has written a monograph in which he compares Venezuelan and African strains of *T. vivax*

SEAGER (p 261) has succeeded in infecting ducks by injection of *T. equiperdum* and refers to the possibility that there may be avian reservoirs of similar mammalian parasites. In comment CORSON states that human and other mammalian pathogenic trypanosomes have successfully been transmitted to various species of birds and that avian blood has been found in nature in tsetse flies. CHEN *et al* (p 872) report observations on parasitaemia and length of survival of mice infected with *T. equiperdum*

VAN DEN BERGHE (p 871) has investigated the infection of chick embryos with *T. evansi* for details the original abstract should be consulted.

ROMANA (p 873) reports on the infection of bats with *S. vespertilionis*

Treatment.

CALVER (p 704) has written a thesis (unpublished) on chemotherapeutic studies in experimental *T. congolense* infections. This has been very fully abstracted. Two strains of the trypanosome were used which differed in pathogenicity and in the course of the infections they produced. The author distinguishes between acute strains (passed from mouse to mouse at the point when the trypanosomes first become uncountable in the blood) and relapse or chronic strains (passed at a later stage of the infection). Treatment was given at various stages of the disease and for this the author used certain compounds of the phenanthridinium series Stilbamidine and quinoline methochloride. The details of these treatments cannot be summarized more satisfactorily than in the original abstract the results indicate considerable value for several of the compounds tested. Attempts to produce drug fastness were not successful. The immunity developed after infection and cure differed in the two strains and was complex even in relation to the homologous strain there was no cross-immunity between the strains. Field trials in Africa with two of the phenanthridinium compounds have been reported, and these together with the author's own work indicate that the drugs are likely to be useful. BROWNING *et al* (p 258) have found that one of the series of phenanthridinium compounds has a curative action in *T. congolense* infections of mice at a dosage much less than the maximum tolerated dose. BROWNING and CALVER (p 259) have taken this work further using two strains of *T. congolense* with somewhat different characters. Treatment was more effective when the trypanosomes were abundant than earlier which suggests that immunity may play a part in the cure. Immunity after cure was much more solid with one strain than with the other and there was no cross immunity. In the field results may depend on the strains of *T. congolense* the stage of infection and other factors. CARMICHAEL and BELL (p 259) have tested this drug in *T. congolense* infections of cattle and advise that it should be given intravenously or intramuscularly. Most of the animals relapsed but retreatment was largely successful. Details are given in the original abstract.

A new phenanthridinium compound prepared by BROWNING was tested in cattle infected with *T. congolense* by CARMICHAEL and BELL (p 260) in Uganda. The results were very good, and cure was obtained in all cases. The subcutaneous route of administration is apparently favoured and though toxicity was not investigated it is believed to be low.

HUFFAKER, C. B. SOTO H. & REY H. Additional Wild-Caught *Anopheles punctimacula* D and K. infected with Malaria Plasmodia in Colombia, South America. *Amer J Hyg* 1945 Sept. v 42, No. 2 107-10. [12 refs.]

The scanty evidence upon which was based the conclusion that *Anopheles punctimacula* D and K is "incapable of transmitting malaria," is briefly mentioned. It amounts to failure to demonstrate malaria plasmodia in 18 mosquitoes after feeding on infected persons.

Since 1938 three natural infections have been reported the present authors record five more. In February 1944 they collected adults from houses and in June the same year from houses stables and baited traps. They supplied the females with 10 per cent. sucrose and kept them alive at 72°F for from five to eight days before dissecting them. The stomachs only were then removed and stored in 50 per cent. alcohol until they could be stained and examined.

In three stomachs very small cysts were seen which would easily have been missed if the females had not been kept alive for some time after capture. Altogether out of 433 stomachs five were found to be infected (1.2 per cent.) but these all occurred in the June dissections (329) which gives an infectivity rate of 1.5 per cent.

The authors conclude that *Anopheles punctimacula* must not be ignored as it may be a dangerous vector of malaria wherever it is produced in abundance.

ROGERS K. B. Concentrating Malaria Parasites in Thin Films. *Brit Med J* 1946 Jan. 5 11-12.

The author describes a technique which he has devised for concentrating malarial parasites for the purpose of facilitating diagnosis. It involves centrifugation in a small tube followed by removal of the packed red cells and some serum in a capillary tube. This tube is centrifuged (2,000-3,000 revolutions) for 20 to 30 minutes. The top portion of the packed red cells is cut off with a little of the supernatant serum. This piece of capillary tube open at both ends is inserted into a specially constructed pipette which has an S-shaped bend to prevent the tube passing to the closed lower end of the pipette. The pipette with the tube in it is centrifuged for 2 to 5 seconds. The blood and serum are driven out of the capillary tube to the closed lower end of the pipette. On cutting off the tip of the pipette the red cells and serum can be blown on to a slide for film making. It is claimed that a concentration of from 5 to 56 times can be obtained. Of 52 positive bloods five were positive only in the concentrated blood film. Those interested in the technique must consult the original paper for further details

METCALF R. L. The Detection of the Plasmodia of Human Malaria in Blood Films by Fluorescence Microscopy. *J National Malaria Soc* Tallahassee Fla. 1945 Sept. v 4 No 3 223-9 3 figs.

The paper describes a method of identifying malarial parasites by means of the fluorescence microscope. Thin blood films fixed in methyl alcohol are stained with berberine sulphate or rivanol. When such films are observed under the fluorescence microscope the malarial parasites are luminous and are thus easily detected. It is claimed that the appearances of the three species

of parasite are much like those seen in Giemsa preparations except for the colour differences. The author suggests that because of its simplicity the method may be of value in routine malaria surveys. Similar observations have been made previously by BOCK and OESTERLIN and by PATTON and METCALF [this *Bulletin* 1944 v 41 545 and 546] C M Wenyon

KLEBERG J *Studies on the Weltmann Reaction in Malaria Cases* *Trans Roy Soc Trop Med & Hyg* 1945 Dec v 39 No 3 221-8 1 fig [36 refs]

The Weltman Coagulation Reaction is an entirely unspecific protein-globalulin reaction but the author considers that it might be of considerable diagnostic value in tropical fevers. The test consists in the addition of 0.1 cc. of haemoglobin free serum to each of a series of ten small test tubes containing graduated ascending dilutions of calcium chloride solution. The tubes are shaken and placed in a boiling water bath for 15 minutes. The reaction is then read. The contents of the tube may be clear faintly opalescent turbid or there may be flocculation. The number of tubes in which flocculation occurs is called the coagulation band. In normal serum the first six tubes usually show flocculation coagulation values of 6 or 7 are normal. If coagulation occurs in tubes with higher dilutions of calcium chloride (tubes 8 9 10) this shift to the right of the coagulation band is indicative of a chronic proliferative process. If there is a shortened coagulation band (tubes 1 to 5 only) such shift to the left is indicative of an acute inflammatory exudative process. The author reports on the results of the test in 25 cases of malaria. Though a malaria attack clinically produces all the features of an acute inflammatory process the W.C.R. showed a shift to the right in 13 cases was normal in 10 and a shift to the left in 2 only. Haemolysis may be responsible for the lengthened coagulation band in malaria. The test is particularly valuable in all haemolytic processes it might be helpful in blackwater fever. The test repeated during the course of a disease may be helpful in prognosis. A succinct description of the technique is given.

PLÖTNER, K. *Ueber die Ursache der Regelmässigkeit des Malariafiebers* [The Cause of the Periodicity of Malarial Fevers.] *Dent Tropenmed Ztschr* 1944 Apr-May v 48 Nos 7/10 148-56 5 figs Norman White

In three cases of malaria intercurrent infections which gave rise to continuous fever during the otherwise apyrexial periods between paroxysms resulted in the disappearance of the malarial fever and parasites during the disappearance of the malarial fever and parasites.

In a patient suffering from quotidian paroxysms after subcutaneous administration of blood containing benign tertian parasites artificial fever was induced during an apyrexial period by intravenous injection of vaccine. After an apyrexial stage of two days following this artificial fever the periodicity of the malarial paroxysms became tertian and, according to the author, one generation of parasites disappeared from the peripheral blood. In two cases of sporozoite induced therapeutic benign tertian malaria however artificial fever had no effect.

The author suggests that an approximate 12 hour period of normal temperature is favourable to the development of *P. vivax* and *P. malariae*. Artificial

fever induction might be useful in conjunction with chemotherapy in frequently relapsing cases. B G Macgregor

ANN TROP MED. & PARASIT 1945 Dec. 31 v 39 Nos. 3/4 157-8. Malarial Research leading to Paludrine. [Editorial.]

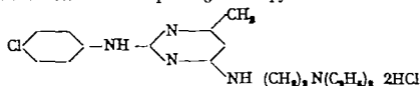

CURD F H S DAVEY D G & ROSE F L. Studies on Synthetic Antimalarial Drugs. I. Biological Methods. II. General Chemical Considerations. *Ann. Trop. Med. & Parasit.* 1945 Dec. 31 v 39 Nos. 3/4 139-58 1 graph. [17 refs.] 157-64. [12 refs.]

In the Editorial Notice a brief outline is given of the researches leading to the synthesis of the new antimalarial drug Paludrine by the Imperial Chemical Industries Limited at Blackley Manchester and of the early clinical trials carried out by the Liverpool School of Tropical Medicine. This work owed a great deal to the initiative and vigour of the late Professor Warrington YORKE who gave much of his time to its welfare. The issue of the *Annals of Tropical Medicine and Parasitology* in which these researches are recorded is dedicated to his memory.

I. In this paper written nearly two years ago the authors deal briefly with the life-cycle of malarial parasites from the point of view of chemotherapy in the light of recent knowledge resulting from intensive studies on bird malaria. Thus a drug may act on the sporozoite stage on the succeeding developmental forms named cryptozoites by HUFF *et al.* [this *Bulletin* 1943 v 40 515 1945 v 42, 538] and referred to as the tissue phase by DAVEY [this *Bulletin* 1944 v 41 365] or finally on the blood forms of the parasite, which are of most interest to the clinician. Whereas in the past drugs were tested against blood-forms, as in the well-known method of ROEHL, which is discussed, JAMES has long emphasized the need for a causal prophylactic which would be effective against the early stages of the parasite. It should not, however, be forgotten that pamaquin and possibly mepacrine were discovered by Roehl's technique. Soon after the introduction of sulphonamides it was shown that certain members of the group had a degree of specificity against human malaria parasites which, however, was not manifested against *P. rodicum* by the Roehl test. The authors decided to use in their test acute *P. gallinaceum* infections in chickens on account of its practicability and the fact that this parasite was in line with the human parasites sensitive to certain sulphonamides as well as to the standard antimalarials, quinine pamaquin and mepacrine. Cross checks on activity were also made on *P. lophurae* infections in ducks and on *P. cathemerium* and *P. rodicum* infections in canaries to determine any specificity of action. The erythrocytic forms found in *P. gallinaceum* infections did not interfere with the test for suppressive drugs on account of the acute nature of the treated infection. In the test which resembles that employed by American workers chicks six days old, were inoculated via a jugular vein with 0.2 cc. of a suspension of parasitized cells containing 40-50 million parasites, from a donor chick with acute infection. Parasites are demonstrable in the blood from the time of inoculation and a peak of parasitaemia occurs approximately four days later. In treating the established blood infection the drug was given orally by catheter in 1 ml. of fluid about 3 hours after inoculation and twice daily on the three following days. In order to assess the activity of an unknown drug comparison was made of the density of infections in six chicks treated with it, in six others treated with mepacrine whose potency was known, as well as

in the same number of untreated controls at the time when the peak of parasitaemia occurs in the latter. It emerged from the author's experimental work with mepacrine in agreement with earlier writers regarding quinine that there was a critical dosage range for this drug. A critical dose was established for each drug tested and compared with the standard mepacrine. The authors regard the critical dose as of the greatest importance it is defined as the minimum dose of a substance which administered according to a particular dosage schedule exerts what is materially the maximum effect of the drug. Other factors were also considered in the case of a new drug such as toxicity for mammals action against other plasmodia and possible specificity of action an interesting case of which is described before clinical tests were made on man. In this connexion their experiences with the drugs 2666 and 3349 (see below) are described. Whether a drug active in *P. gallinaceum* infection will be active in human malaria or whether different drugs given under a similar dosage schedule are absorbed to the same extent cannot be foretold. Nevertheless the test employed has led to the discovery of new and potent anti-malarials.

II The authors state their two main objectives to be the discovery of a true prophylactic drug in malaria and of other drugs more potent than existing types for use in clinical practice. The approach to the latter problem is described in this communication. Following the discovery of pamaquin and mepacrine which contain respectively a quinoline and an acridine nucleus synthetic work has centred mainly on derivatives of these types although other heterocyclic ring-systems have been studied. A drug more potent than mepacrine was not however discovered. The presence of basic side-chains attached to the different ring systems was shown to be of great importance for antimalarial activity by the work of SCHULEMANN and collaborators. The present authors have devoted their attention to certain derivatives of pyrimidine. Substances containing this ring-system are often of great physiological importance. Derivatives of molecular weight 300-400 containing a substituted phenyl group and basic side-chain were found to be inactive in *P. gallinaceum* infections whereas the corresponding anilino pyrimidines of which 2666

was an example showed antimalarial activity which persisted in spite of wide variations of the prototype. As stated by the authors. The prerequisite for antimalarial activity therefore appeared to be the simultaneous association with the pyrimidine nucleus of not only a basic alkylamino group but also an aryl group linked through a grouping capable of prototropic change. When the—NH—linkage of the above compound was replaced by a guanidine group —HN—C(=NH)—the compound 3349 (2-*p*-chlorophenylguanidino-4-β-diethy-

NH

laminoethylamino-6-methylpyrimidine) was obtained which was active in bird malaria and the three common forms of human malaria when used as the dihydrochloride. This substance also offers possibilities of tautomeric change similar to those of 2666 above with which antimalarial activity may be associated a view which is discussed in relation to possible tautomeric changes in mepacrine. Certain views of others on the mode of action of this powerful antimalarial are given. The present authors believe that the pyrimidines 2666 and 3349 may undergo corresponding degradation changes *in vivo* and give

rise to compounds with marked similarities to riboflavin. Work is in progress to elucidate the mechanism of antimalarial action of these new substances and their possible relation to the yellow enzyme systems. *J D Fulton*

III. A Preliminary Investigation of the Therapeutic Action of 3349 on Acute Attacks of Benign Tertian Malaria. *Ann Trop Med & Parasit.* 1945 Dec. 31 v 39 Nos. 3/4 165-8 IV. A Preliminary Investigation of the Therapeutic Action of 3349 on Acute Attacks of Malignant Tertian Malaria. *Ibid* 169-72 V. Further Investigation of the Therapeutic Action of 3349 on Benign Tertian and on Malignant Tertian Malaria Infections. *Ibid* 173-9 7 figs. VI. A Comparison of the Therapeutic Actions of 3349 and of Mepacrine Hydrochloride on Acute Attacks of Benign Tertian Malaria. *Ibid* 180-81 2 figs

III In view of the activity of compound 3349 in *P. gallinaceum* infections described above tests were now carried out in human malaria. The first trials were made on a strain of *P. vivax* which was employed in malaria therapy and had been passaged by blood inoculation. Such infections are easily cured. Five neurological cases were treated orally with 0.2 gm. of 3349 (see Part II) thrice daily on seven consecutive days while another case received half this amount of drug. The dosage was based on toxicity data for the drug in animals and it was believed to be not more toxic for mice than mepacrine. In all cases there was a rapid fall in temperature and disappearance of the parasite from the peripheral blood, with no marked evidence of toxicity. Infections with *P. vivax* in healthy males which had been acquired in different parts of the world were next treated. These infections were of several weeks or months' duration and most of the patients had been treated previously with standard antimalarials or had been given mepacrine prophylactically. All the patients were suffering from clinical malaria and had to be kept in bed. One man was experiencing his first severe clinical attack. Observations were made before treatment was started to verify that the attack was not ending spontaneously. Seventeen acute cases of naturally acquired benign tertian malaria were treated orally with 0.2 gm. of 3349 thrice daily for seven days. A thick blood film of each patient was examined daily while he was in hospital and twice weekly during convalescence. The clinical attack was in each case rapidly terminated by this treatment. Of seven other cases treated with half the dose three relapsed in 2-3 weeks three others remained well for 5-8 weeks while the seventh showed no response to the treatment but was clinically cured with the larger dose. There were no toxic symptoms with the smaller dose. Further courses of drug were given to some patients to find out if toxic symptoms occurred. One received 0.2 gm. of 3349 thrice daily on two consecutive days each week for 9 weeks and 15 others 0.1 gm. twice daily for periods up to six weeks. The only untoward symptoms encountered were mild colic and diarrhoea or frontal headache. There was a relapse in one case seven weeks after the first course while receiving 0.2 gm. of 3349 daily.

IV As the drug 3349 had shown activity in cases of benign tertian malaria treatment was now begun on cases of malignant tertian infection acquired in W Africa or in the Mediterranean. Most of the men had been treated previously with standard antimalarials. The duration of the infections was from a few weeks to some months before treatment was begun but in some patients the first clinical attack of the disease was treated. The authors consider that it has not been clearly shown whether a primary attack of malignant tertian malaria in a patient who has had no prophylactic drug-treatment, or a delayed primary attack in one who has been so treated, is more responsive to chemotherapy than a patient suffering from relapse subsequent to previous courses

of treatment Their experience leads them to believe that the immediate response to an effective drug is similar in each case. No patients with infection of long standing were included in this study. The conditions for trial were the same as in Part III above. The clinical attack was successfully treated in 25 cases of malignant tertian malaria by 0.2 gm. of 3349 orally thrice daily for seven days. Nine of the patients were then discharged. In five others there was no relapse during a period of 3½ months. Two cases which relapsed in 3-4 weeks were retreated and responded to the above dosage whereas half the amount of drug proved unsatisfactory in curing clinical attacks or in preventing recrudescence. The remaining nine received a second course of 0.2 gm. of the same drug by mouth daily for 3-6 weeks and remained well and free from parasites during that period. The higher dosage caused slight colic and diarrhoea and transient headache in a few instances at the start of the treatment. In 15 cases of the same infection treated orally with 0.1 gm. of the drug thrice daily for seven days the results were less satisfactory as the clinical attack was in some cases not arrested, while other patients experienced a rapid recrudescence of the attack. On this dosage there were no untoward symptoms caused by the drug.

V Further trials with 3349 given orally have now been carried out in 206 cases of benign tertian and in 61 cases of malignant tertian malaria under the same conditions as previously observed. Data have been collected on the relapse rates of patients treated with this drug. Details of the benign tertian cases are dealt with first. Many were treated for delayed primary attacks consequent on the discontinuation of prophylactic mepacrine. The effects of different dosage schedules of the drug on the temperature and on the number of asexual forms in the blood are recorded in a number of graphs. Retreatment of relapses was successful and provided no evidence of development of resistance to this drug. Sexual forms of the parasite were unaffected by 3349. The relapse rate in this form of malaria after effective clinical treatment was over 70 per cent in 126 cases within a period of eight weeks and was fairly constant in the different classes treated. In the case of malignant tertian malaria 15 acute attacks were treated with 0.1 gm. of 3349 thrice daily for seven days. As in benign tertian this dosage was unable to control all the attacks and asexual parasites were present in four of the cases on completion of treatment. Double this dose of drug was effective in 32 of 33 cases. Twenty seven of 28 attacks were successfully treated by 0.5 gm. of the drug given each twelve hours for 2-7 days. Good results were obtained in four patients treated with 1.0 gm. of drug on two occasions with a twelve hour interval between doses. Relapses were noted under all dosage schedules except in two cases when 1.0 gm. doses were given. The drug showed no activity against the crescent forms. Only the mild toxic symptoms due to the drug were encountered, as noted in the earlier studies and they did not prevent continuation of treatment. One patient after a dose of 1.0 gm. of the drug had severe diarrhoea.

VI When the action of 3349 was being tested on acute attacks of benign tertian malaria alternate and unselected cases were for a time treated with mepacrine hydrochloride. Both drugs were given orally and their administration was carefully supervised. Two hundred and thirty five cases were treated with 3349 in doses regarded as clinically effective as follows —

95 cases	0.2 gm. of 3349 thrice daily for 7 days.
28	0.5 gm. 3349 12-hourly for 2 days
54	0.5 gm. 3349
54	0.5 gm. 3349
4	1.0 gm. 3349
	1 day

For comparison 102 cases received 0.2 gm. mepacrine thrice daily for 2 days and then 0.1 gm. mepacrine thrice daily for 5 days—a dosage previously employed by the authors on an extensive scale in the control of all types of acute malaria infection. The experimental details for each drug are recorded in Figs. A and B in the paper. The following is the authors' comment—

A study of Figs. A and B shows very comparable activity of 3349 and of mepacrine hydrochloride in the arrest of acute attacks of *P. vivax* infection. In each series of cases gametocytes were observed to persist in the peripheral blood in about half the cases for periods up to a week after the end of treatment. In neither were the patients unduly inconvenienced by side-effects resulting from the treatment. The absence of yellow staining of the skin in those men treated with 3349 was held by them more than to counterbalance the mild colic or diarrhoea which some of them experienced for the first day or two of this treatment.

VII. A turbidimetric method for the estimation of 3349 in biological material has been developed which is claimed to be simple and accurate. Reference is made to two other methods of estimation and also to a colorimetric method which is described in Part VIII of this series. The present method is accurate to within 10 per cent. and its sensitivity is given as about 2 μ gm. of 3349 in any biological material. It is founded on the fact that many basic substances form insoluble salts with complex acids. 3349 was found to give precipitates with a number of organic and inorganic acids and the potassium mercuri-iodide reagent of GEATSKOW [this *Bulletin* 1938 v 35 569] was found to be the most suitable in that the suspension formed was reasonably stable at high dilution. Precipitation of the base occurs in acid or alkaline solution with this reagent. It was brought about in N/10 hydrochloric acid since extraction was carried out with this reagent and results were best as regards opacity of the suspension with that particular concentration of acid. When formed, the suspensions were examined in a direct reading photoelectric colorimeter the percentage of light transmitted being in approximate agreement with the galvanometer deflections. The best results were obtained if galvanometer readings were made at 5-10 minutes after formation of the suspension and the temperature of the reaction or colour of the incident light did not affect the readings to any extent. To obtain the base from the basified biological material continuous extraction with ether was used and the solvent was completely removed before dissolving the base in N/10 HCl. The method can be applied to blood, urine and tissues of animals after administration of large doses of drug. It is not however suitable for human blood or plasma as the amounts of drug present in these substances are too small and the colorimetric method of estimation described in Part VIII is then recommended. In the preparation of a standard curve which could be maintained for permanent reference, the amount of 3349 base present in μ gm. was plotted against deflections of the galvanometer. 2 ml. standards of the base in solution in N/10 HCl containing 0-50 μ gm. in twice

different tubes were used in its construction and the contents mixed with 0.2 ml of mercuric iodide reagent. The deflections were read for each standard 5 minutes after mixing when the deflection of the blank had been made to read 100 on the galvanometer scale of the colorimeter. [The complete details of the method cannot be given here.]

VIII A colorimetric method more suitable for the estimation of 3349 in blood and plasma than the turbidimetric method outlined above is described. It depends on the hydrolysis of the substance to *p*-chloroaniline which is then diazotized and coupled with *N*- β -sulphatoethyl-*m*-toluidine to give a red dye. As little as 0.4 μ gm of the drug is estimable in biological material. It was shown by large scale experiment that quantitative hydrolysis of 3349 by *N*/1 HCl to *p*-chloroaniline did not occur under normal pressure but was achieved by hydrolysis with *N*/2 HCl under a pressure of 20–25 lb for 12 hours. In the extraction previous to hydrolysis a mixture of benzene containing 2 per cent of ethanol gave 100 per cent recovery of 3349 from biological material by single extraction after the material had been basified and rendered less viscous by warming at 50°C for 30 minutes. All the reagents employed were of the highest purity. A standard reference curve was prepared in which μ gm of 3349 per ml were plotted against drum readings of the Spekker absorptiometer and against galvanometer deflections in the case of the photo-electric colorimeter. In these determinations solutions containing 0–20 μ gm of 3349 per ml in *N*/2 HCl were hydrolysed in sealed ampoules under the conditions described above in volumes of 1–2 ml. On cooling 1 ml. aliquots were partially neutralized diazotized and coupled and after 10 minutes the yellow colour present was changed to red by 4 drops of concentrated HCl. The volumes were then corrected and readings made on the instrument selected, not more than 1 hour after coupling while using a filter with maximum transmission at 510 $m\mu$ since the absorption maximum of the coloured substance was at 507.5 $m\mu$.

For estimation in the case of blood, 1–7.5 ml. are used and the blood is laked before being made alkaline. The next steps are as described above. The same principles are employed for estimation in the case of plasma, urine, bile, tissues and faeces. The four last may contain large amounts of drug. [Details are recorded in the paper but cannot be given here.] Mepacrine in high concentration may interfere with results and also phenacetin and procaine. Most tissues contain no reacting substances but blood may give a high blank. The recoveries of drug from blood, plasma, tissues, faeces and urine approached theoretical.

IX Using the turbidimetric method for the estimation of 3349 the authors measured its urinary excretion in four normal volunteers each of whom was given 500 mgm orally twice daily for 4–5 days. Nausea, epigastric pain and diarrhoea occurred and one subject vomited after the eighth dose. The urine of volunteers was collected regularly for 7 days previous to and for 14 days after treatment started, and irregularly till the amount of drug present was minute. While the drug was being taken there was a diminution in urinary output probably as the result of diarrhoea but there was neither glycosuria nor albuminuria. The percentage of the daily intake of drug excreted in the urine continued to increase while the doses were maintained but it was not constant by the fifth day when dosage ceased. After that time there was a rapid fall in output. Minute amounts of drug were still present in the urine 23 days after the start of treatment which suggested that it was being retained in the tissues. About 4 per cent. of the total drug administered was found in the urine of each volunteer and likewise in that of treated rabbits and rats in its manner of excretion 3349 therefore resembles mepacrine. Since it is shown in Part VII that *p*-chloroaniline was a hydrolytic product of 3349

and possibly acetone as well, the excretion of aromatic amine of total amine, and of acetone was measured during the experiment. Paradoxically the amount of "total amine found was less than that of "free amine possibly due to the presence of esters of aminophenols. There was a significant increase in excretion of aromatic amine while the drug was being taken, but it represented only a very small conversion of 3349 to *p*-chloroaniline. There was no evidence that 3349 gave rise to acetone in the human subject. It is well known that many aromatic substances are converted in the body to hydroxyl derivatives which are then excreted as aryl sulphates or glucuronides. Measurements of the amount of detoxication of 3349 but none was obtained. A search for metabolites of 3349 was also made in urine but only the parent substance was isolated. By quantitative experiments in the isolation of added 3349 from urine it was shown that the substance estimated as 3349 by the turbidimetric method of Part VII was indeed that substance possibly contaminated with very small amounts of basic metabolites as judged by ultra violet absorption spectra. Work in progress suggests that most of the 98 per cent. of administered 3349 still unaccounted for may be present in faeces. The possibility of formation of a hydroxyl derivative of the parent substance excluded. The deamination of the latter or alteration in the side-chain is however not excluded.

SPINKS A & TOTTER MARV M. XII. Determination of N_1 *p*-Chlorophenyl- N_2 -Methyl- N_3 -Isopropylbiguanide (4430) and N_1 *p*-Chlorophenyl- N_2 -Isopropylbiguanide (Paludrine) a Preliminary Report. *Ibid.* 220-24 1

\. In this paper a preliminary account is given of the chemical considerations leading to the synthesis of biguanides with marked action on the blood and erythrocytic forms of certain avian malaria parasites. The chemical constitutions of two of these substances are as follows —

Both are colourless, crystalline substances soluble in water. The action of the former is analogous to that of certain sulphonamides in avian malaria, whereas the latter has some unique properties in this infection which suggest that an advance has been made in the prevention and treatment of malaria. While 4430 is a causal prophylactic against *P. gallinaceum* only and is ineffective against the blood forms of *P. cathemerium* 4888 acts both as causal

prophylactic and as a therapeutic agent in the four types of avian malaria studied. The probable life-cycle of the malaria parasite in the vertebrate host as outlined by a number of workers including HOFF *et al* [this *Bulletin* 1943 v 40 815 1945 v 42 538] and DAVEY [this *Bulletin* 1944 v 41 385] leads the authors to believe that drugs with an action against exo-erythrocytic forms are of paramount importance and that on this action causal prophylaxis and prevention of relapses probably depend. JAMES especially has long put forward similar views although the presence of such forms has not yet been satisfactorily demonstrated in human malaria. After the synthesis of certain pyrimidine derivatives described in Parts I and II of this series which contained an $-NH-$ (imino group) or $HN-C-NH$ (guanidino group) between the

$$\begin{array}{c} \text{NH} \\ \parallel \\ \text{HN}-\text{C}-\text{NH}-\text{C}-\text{N} \end{array}$$

ring systems theoretical considerations led the authors to the synthesis of compounds with a new linkage—

substitution of other heterocyclic ring-systems than pyrimidine opened further possibilities but the authors stress the practical need for simplicity of synthesis and the retention only of groups necessary for antimalarial activity. It was found that the pyrimidine ring was not essential. Biguanides are easily synthesized, and in this reaction ammonia or an amine takes part. The first member of the new series proved inactive in *P. gallinaceum* infection on account it was believed, of its too strongly basic character. By selecting suitable amines for the reaction the active substances 4430 and 4888 were obtained. [The latest views of the authors on these matters have recently been given to the Chemical Society.]

In the case of *P. gallinaceum* and *P. relictum* sporozoites have been shown to undergo a cycle of development in tissues and have been designated by the authors as primary exoerythrocytic (e e) forms. A causal prophylactic drug would act against either of these forms. No drugs are yet known which act against sporozoites but the properties especially of 4888 suggest that it may act as a causal prophylactic in human malaria. When the development of primary e e forms is completed the blood is then invaded and during multiplication in the latter site there is a concomitant increase in tissue forms. From the reaction of the tissue forms to drugs they appear to differ from primary e e forms they have been designated secondary e e forms and may be derived from blood forms as they can be transmitted by blood inoculation. Since a radical cure of avian malaria is not easily obtained in which respect it resembles benign tertian malaria the presence of secondary e e forms in the latter infection although not yet demonstrated may be the explanation of its failure to effect cure. The search for a drug active against the blood forms of human malaria but without the practical drawbacks of mepacrine both as regards dyeing properties and the many steps in its synthesis has not been neglected. A comparison of the action of 4430 and 4888 as causal prophylactics and in treatment of blood infections has been made with that of quinine mepacrine and sulphonamides in four species of avian malaria and the results are given in a table. The properties of the two new drugs were such as to justify their trial in human malaria.

XI This note records the first trials in human malaria of the new drug 4430 described in Part X. The early dosages ranged from 20–500 mgm. orally thrice daily without evidence of serious effects. When 1 gm doses were given more or less severe toxic symptoms were encountered. Benign and malignant tertian malaria naturally acquired was treated in healthy subjects after their return from service overseas. Most of them had taken mepacrine

Tropical Diseases Bulletin

or quinine prophylactically and there was in some cases a history of previous chemical attacks. The conditions of treatment were the same as those described in Part III and subsequent papers of this series. In 44 cases of benign tertian malaria the clinical attack was rapidly cured within 72 hours and the peripheral blood was freed from parasites within 96 hours after the start of treatment but gametocytes were present after 6 days. The details of these cases are recorded in tabular form. More than half the cases relapsed independently of the dosage given. In nine cases of naturally acquired *P. falciparum* infection similar results were obtained. The crescent forms appeared to be unaffected by the drug. One-third of the cases were known to have relapsed with different dosages but in two receiving the highest dosage given for 1 week, no relapse occurred. Doses of 1 gm or more of the drug daily caused nausea and vomiting. The highest doses gave rise to loss of pain, vomiting, sweating, *icterus*, albuminuria and haematuria or the presence of red cells in the urine. With copious fluids, recovery was complete in 24 hours. In subsequent cases a liberal fluid intake when the drug was being administered avoided renal complications.

XII. This is a preliminary report on the estimation of the two drugs 4430 and 4888 (Paludrine) described in Part I of this series. On account of the presence of a β -chlorophenylguanidine residue which can be hydrolysed to β -chloroaniline apparently more readily than in 3349 the same colorimetric method of estimation can be employed as for the latter substance. The two newer drugs are recoverable quantitatively from blood, plasma, and tissues with the same method of extraction. In their case $\sim 1/4$ HCl is used for both extraction and hydrolysis and partial neutralization becomes unnecessary. Details of the method are given for blood, and it can be adapted to other biological materials. As before, it consists essentially in taking, basifying, rendering less viscous by heat, and then extracting the base with benzene-ethanol. An aliquot is then hydrolysed under pressure in a coloured substance which is estimated in a photoelectric colorimeter not more than one hour later and compared with a standard curve compiled from known amounts of material. On account of lower molecular weights of 4430 and 4888 smaller amounts can be estimated than in the case of 3349 and the levels of the former are actually higher in blood, plasma and urine but not in faeces and tissues. The amounts estimable depend on the apparatus available. Some instruments allow 0.2 μ gm. in aqueous solution to be estimated, but the sensitivity of the method can be increased 3-5 times by special apparatus. Purity of reagents and cleanliness of apparatus should be used as check. Recovery from plasma and urine approached the theoretical while the accuracy was somewhat lower in the case of blood and tissues.

Results of a Preliminary Investigation of the Therapeutic Action of 4888 (Paludrine) on Acute Attacks of Benign Tertian Malaria. *Ann. Trop. Med. & Parasit.* 1945 Dec 31 v. 39 Nos. 3/4 225-31, 4 figs.
- MARGRAITH B. G., ADAMS, A. R. D., KING, J. D., TOWNSHEND R. H., DAVEY T. H. & HAYWARD R. E. XIV. Results of a Preliminary Investigation of the Therapeutic Action of 4888 (Paludrine) on Acute Attacks of Malignant Tertian Malaria. *Ibid.* 1945 Dec 31 v. 39 Nos. 3/4 232-8, 1 fig.
- XIII. This preliminary report describes the first clinical trials with "Paludrine" (4888) given orally in acute attacks of benign tertian malaria. The

tests were initiated when it was found that the drug was probably curative in *P. gallinaceum* infections of chickens. The patients were Service men suffering from primary attacks of benign tertian malaria or from relapses. No patient in whom the clinical attack had lasted more than one week was included in the series. Suppressive mepacrine had been taken by most and some had been treated with the standard antimalarials in all cases more than two weeks before hospitalization. The same conditions of treatment were observed as described in Part III etc. of this series. Experimental data in animals suggested that 40 mgm per day would be a safe dose in man and 20 mgm were therefore given 12 hourly on 14 consecutive days a treatment which proved clinically effective. The dosage was increased step-wise to 700 mgm. twelve hourly in later cases and careful watch was kept on the patients for any untoward symptoms. Doses of 10 mgm. 12-hourly were successfully employed in three cases but below this level clinical results were variable. Blood films were examined twice daily till parasites disappeared, and thereafter daily while the patient was under observation. The detailed results of treatment of 147 cases with doses ranging from 10 to 700 mgm. 12 hourly for 14 or 28 days are recorded graphically along with those for 183 similar cases treated with mepacrine in doses of 0.8 gm. daily for two days followed by 0.3 gm. daily for 10 days. Paludrine controlled the acute attacks over the range studied as effectively as mepacrine. Toxic symptoms seen in a few cases included vomiting and epigastric pain but it was never found necessary to interrupt treatment and regular urine examinations disclosed no abnormality. Estimations of drug concentration in whole blood, plasma and urine have been made following single doses of 50 and 500 mgm. In whole blood the estimations were unreliable as previously observed for mepacrine and were therefore abandoned. The plasma and urinary concentrations after the standard therapeutic dosage with 50 or 500 mgm. 12-hourly for 14 days were also determined. In these cases the plasma concentration rose rapidly and remained fairly steady from the fourth to fifth day of treatment. When treatment ended there was a rapid fall in the concentration. The urinary output followed a similar pattern and in urine the drug was detectable in some cases for nine days after the end of treatment. The fall in plasma level and in urinary output are more rapid than in the case of mepacrine.

XIV The treatment of 22 cases of recently acquired malignant tertian malaria with Paludrine (4888) orally is reported in this note. Sixteen of the patients had no previous history of malaria the others had had one previous attack of malignant tertian malaria. Seven had received no suppressive treatment while the remainder had taken quinine or mepacrine. No anti-malarial treatment had been given for at least two weeks before treatment with Paludrine was begun. All the subjects were kept in bed and the conditions of treatment as outlined in Part III were observed, except that in some cases the patients were ill on admission and treatment was started within 24 hours. The first dosage schedule tried was 50 mgm. 12 hourly for 14 days and during treatment the patient was encouraged to drink plenty of fluids. The clinical attack was controlled in all cases with the above dosage. Later cases were given 200 500 or 600 mgm doses in the same way. Therapeutic results were judged as in previous trials. With this treatment asexual parasites rapidly disappeared from the peripheral blood temperature was controlled and the condition of the patient rapidly improved. Gametocytes were unaffected. The clinical results obtained so far are comparable with those in benign tertian malaria. A few patients vomited after the drug but probably not on account of it as vomiting ceased with improvement of the clinical condition. There were no other untoward effects.

KELSEY F. E., OLDHAM F. K. & CULLINC E. M. K. Studies on Antimalarial Drugs. The Metabolism of Quinine and Quinidine in Birds and Mammals. *J Pharm & Exper Therap* 1945 Oct. v 85 No 2, 170-75 1 fig

In previous papers Kelsey and Oldham [this Bulletin 1944 v 41 260] have investigated the ability of tissues of different species of animals to metabolize quinine *in vitro* and have suggested that there is a probable relationship between *in vitro* and *in vivo* metabolism. In a similar way *in vitro* studies have now been made on the metabolism of quinidine—the optical isomer of quinine—by tissues of various birds, rats and rabbits. Tissues were homogenized in a Waring Blender in Ringer Locke solution and filtered through gauze. Aliquots representing different weights of tissue were mixed with 0.1 mgm. of the two alkaloids in 10 cc. Ringer-Locke solution which was used to make the total volume up to 20 cc. After incubation for 6 hours at 38–40°C. the percentage degradation of these substances was estimated by a method previously employed by the authors. In the *in vitro* studies adult rabbits, chickens and ducks were given 10 mgm. of the alkaloids per kilogram intravenously and were sacrificed 10 minutes, 1 hour and 4 hours after injection of the drug. Post-mortem degradation in the weighed tissues was prevented by 3 per cent. NaOH. *In vitro* it was found that quinine was more readily metabolized than quinidine by rat and rabbit tissues, while the converse was true when tissues from various birds were used. The rabbit metabolized quinine more rapidly than quinidine *in vitro* whereas in the duck and chicken both appeared to be metabolized at similar rates, the rate in the duck being slower than in the chicken. Papers by KELSEY *et al* [this Bulletin 1944 v 41 11], WALEZKY & BROWN [ibid. 1944 v 41 183] and by HIAIT & QUINN [ibid. 1945 v 42, 778] are of interest in this connection. The distribution of these alkaloids between red cells and plasma in the case of ducks and chickens was found to be different. These experiments show that the fate of the two drugs in the chicken and duck is not identical and the results of antimalarial tests in the two species may thus be different.

DEARBORN E. H. & MARSHALL, E. K. Jr. The Degradation of Quinine in the Duck, Chicken and Dog. *J Pharma. & Exper Therap* 1945 Oct., v 83 No. 2, 202-5. 12 refs.]

Different methods for the estimation of quinine in the blood and tissues of animals have been described [this Bulletin 1944 v 41 11 188 260 1945 v 42, 778]. In some of these cases the method of assay has included degradation products of the alkaloid. In the present investigation quinine was administered to ducks and chicks by the drug-diet method of MARSHALL *et al* [this Bulletin 1943 v 40 223] or intravenously and by the latter method to dogs. By the use of selected methods devised by BROWN and UNDERHILL for the estimation, the evidence obtained suggests that more than one degradation product of the alkaloid was formed. By the first method [this Bulletin 1943 v 40 821] total acid-soluble fluorescence is estimated by the second, fluorescence after alkaline extraction and in the third, which proved most reliable for the estimation in plasma, the base is made to combine with methyl orange after alkaline extraction (*J Biol Chem* 1945 v 158 705). The quenching of fluorescence by salt in the first method suggested that only traces of the degradation product described by KELSEY *et al* [this Bulletin 1944 v 41 923] were present, and this was supported by other evidence. The concentration of "quinine" in the plasma of ducks, chicks and dogs was estimated by each method, and also that in the liver of chicks and ducks. By the use of what was termed "quinine oxidase" of rabbit liver by KELSEY and OLDHAM [this

Bulletin 1944 v 41 260] which converts quinine to a 2-hydroxy derivative as shown by MEAD and KOEFFLI [this *Bulletin* 1945 v 42 9] successful degradation of quinine was accomplished in duck plasma, but only to a limited extent in plasma of chicks or dogs

From the results obtained by the three different methods of estimating "quinine" the authors conclude that —

- (1) There are probably at least two degradation products of quinine to be found in the duck after administration of quinine.
- (2) The degradation of quinine appears to be qualitatively similar in ducks, chicks and dogs

MERGEVER, J C. Psychosis following Administration of Quinaerine Hydrochloride for Malaria. *Neuropsychiatric Study of a Case War Medicine* Chicago 1945 Oct v 8 No 4 250-52. J D Fulton

A soldier 25 years of age suffered from a primary *P. falciparum* infection and was treated with quinaerine (mepacrine). During a period of five days he received 2.8 gm. On the fifth day signs of mild excitement appeared he became very talkative his speech was rambling and at times disconnected and it was impossible to keep him in bed. A sedative was given quinaerine was stopped. The excitement increased the next day euphoria and hyperactivity necessitated his being placed in a locked ward. The hyperactivity gradually gave way to a confusional state which bordered on depression he became disoriented for time place and person. His replies to questions became slow and reflected inner confusion. A possibility that cerebral malaria might be the cause of the psychosis prompted the administration of quinine. For six days his condition changed but little then gradual improvement began. In all the mental disturbances lasted 14 days before recovery was complete. Several interviews charged from hospital a fine tremor of the hands persisted. When he was discharged his recovery failed to reveal anything psychiatrically abnormal and there was no antecedent history of psychiatric factors which might have predisposed to the onset of mental symptoms. No recurrence of the symptoms had been noted three months after recovery [See also this *Bulletin* 1945 v 42 9 1946 v 43 297] Norman White

ZYLMAN, G. In vitro—and in vivo—Versuche über die hämolytischen Eigenschaften der synthetischen Malariamittel. [*In vitro* and *in vivo* Experiments on the Haemolytic Properties of Synthetic Remedies for Malaria.] *Deut Tropenmed Ztschr* 1944 Jan. 1 v 48 Nos 1/2 7-18 [15 refs]

This paper contains a brief review of the German literature on the subject. The *in vitro* experiments were designed to compare the lytic action in human cells (from normal persons and patients with M T and B T malaria) of equivalent serially diluted solutions of quinine atebirin plasmoquine and a Priparat x.

Quinine had a lytic effect on all red cells over a range of concentration of 1/50 to 1/800 molar. Atebrin lysed normal red cells over a range of concentration of 1/50 to 1/200 molar. It lysed cells from both B T and M T patients at dilutions of up to 1/400 molar. The author concludes that the haemolytic effect of atebirin is more pronounced on cells from malaria patients than on those from normal subjects. (Three normal persons three M T cases and eleven B T cases were examined.) Plasmoquine had little effect except for a very slight lytic action in the middle range of concentrations. Priparat x had no lytic action. The author attempted to repeat with atebirin KOCIR and KIKUTH's experiments with quinine [this *Bulletin* 1929 v 26 1028]. Atebrin by itself had

Tropical Diseases Bulletin

no lytic effect. Ambocceptor gave rise to haemoglobinaemia in one animal, and haemoglobinuria in two (out of four). Ambocceptor and atabrin injected together gave rise to haemoglobinaemia in three, and haemoglobinuria in two animals (out of four). The author considers that this results indicate that atabrin has a strengthening effect on the haemolytic action of the ambocceptor. He points out that more *in vitro* experiments are required to substantiate this. [No account of the composition of Preparat X is given, presumably because the paper was published during the war.]

MOHR, W. Atebrin-Leberempfindlichkeit. Hypersensitivity to Atebrin.] *Dtsch. Tropenmed. Ztschr.* 1944 Apr-May v 48 Nos. 7/10 177-82.

The author reviews the available literature on atabrin sensitivity and notes that with the usual dosage régimes, evidence of true sensitivity is very rare. Atebrin poisoning is not common even after high dosages. In the literature reviewed, which includes an account of malaria in German troops in the recent war, only three cases of idiosyncratic allergic reactions to atabrin are described.

The author describes a case in which the patient developed a resistant urticaria after atabrin administration for the treatment of malaria (species of parasite not determined, but thought to be *Plasmodium falciparum*). Skin tests showed this patient to be sensitive to atabrin, but not specifically; he was also sensitive to quinine (to a lesser degree) and to a variety of food substances including meat and mushrooms.

BERCOVITZ, Z. I. Malaria complicated by Pneumonia. Treatment with Sulphadiazine and Atebrin. *Ann. Intern. Med.* 1945 July v 23 No 1 79-82.

This is a case report of a patient who suffered concurrently from *P. falciparum* malaria and lobar pneumonia, type 7 pneumococcus. The administration of atabrine did not in any way influence the effect of sulphadiazine over a period of 12 days. Atabrine 0.1 gm. daily was given for 22 days while he was under treatment for pneumonia and for 60 days on two occasions subsequently without harmful effect. Reference is also made to another similar case in which atabrine and sulphathiazole were used with success. Norman White

COXON, R. V. & HAYES, W. Investigation into the Efficacy of Sulphadiazine in the Treatment of Malaria. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1945 Dec. v 39 No 3 195-205. 2 graphs.

Twenty cases of malaria, including fresh and relapsing cases of benign tertian and of malignant tertian, and one quartan infection were treated with

sulphadiazine. Ten cases receiving only non-specific symptomatic treatment served as controls. Comparison was also made with results achieved by quinine-atebrin plasmoquine treatment. The dosage of sulphadiazine in most cases was a loading dose of 5 gm. in the first 4 hours followed by 1 gm. 4-hourly [apparently for 12 days]. With this dosage the concentration in the blood remained at approximately 10 mgm per 100 cc. throughout the course.

For the enumeration of parasites an absolute method of counting was used: oxalated blood was drawn up to the 20 cmm. mark of a Sahli haemoglobinometer pipette and then discharged on a slide and spread accurately and evenly over an area of 2 sq cm. The film was allowed to dry on a level surface. Before dehaemoglobinized with distilled water and stained by Field's stain. Before a sample of blood was reported negative at least 100 fields representing 0.5 cmm. blood were examined. The advantage of this thick film method over the thin was shown in the first twelve cases treated with sulphadiazine: the average day after the beginning of treatment on which the blood first failed to show parasites was 3.7 by the thin and 8 days by the thick film method.

The average duration of fever after commencement of treatment with sulphadiazine was 4½ days in *P. vivax* infections, 6 days in *P. falciparum* infections. Of the untreated controls four spontaneously lost their fever within 12 days of onset in the remaining six the fever was virtually unaltered in degree at the conclusion of the 12th day.

The average time for the blood to become parasite free (asexual forms) after the beginning of treatment was 8 days for both *P. vivax* and *P. falciparum* infections. This does not refer to gametocytes. None of the untreated controls was free from parasites within the 12-day period of observation. In nearly all sulphadiazine treated patients the parasite count began to fall soon after the commencement of treatment and steadily declined to zero. In only one case did the parasites appear to be resistant to the drug. With quinine there was a complete clearing of the blood within 5 days. Gametocytes appeared to be completely unaffected by sulphadiazine. Several patients were given higher doses than the standard *viz* a maintenance dose of 2 gm. 4 hourly thus securing blood levels of 17-20 mgm per 100 cc. The response was not materially different from that obtained by the standard dose.

Of the 20 cases treated with sulphadiazine 15 relapsed within one month from the end of treatment. Fifteen cases that had received standard army treatment—quinine 4 gm. atebriin 1.5 gm. and plasmoquine 0.15 gm. over a period of 14 days—only one relapsed during a period of one month.

The only complications of treatment apart from vomiting in a few patients were renal. Four patients had renal colic, two of these had haematuria but no crystals of the drug were found in the urine. In no case was there a dangerously low white blood cell count. Sulphadiazine has definite antimalarial properties but the action is inferior and slower than that of either quinine or atebriin and treatment with it is followed by a much higher relapse rate. The inquiry revealed that the corrected erythrocyte sedimentation rate is no value in assessing the probability of relapse after treatment in malaria.

Norman White

ENSON D S The Use of Calcium Gluconate in the Treatment of Malarial Chills. Puerto Rico J Pub Health & Trop Med 1944 June v 19 No 4 602-13 2 figs [20 refs] [Spanish version 614-25]

most distressing symptom of malaria is the chill that usually precedes fever. These chills may last from a few minutes to over three hours. The reports the results of treatment of malarial chills.

As soon as possible after onset of the chill, 10 cc. of a 10 per cent. solution of calcium gluconate is given intravenously very slowly. Fifty trials were carried out on 40 patients and the results are tabulated. In only 2 trials did calcium fail to have an observable effect, and in both these the chill had lasted some time before treatment was given. All cases treated within 5 minutes of the onset of the chill showed complete relief within an average time of 3.7 minutes after injection. If the injection was delayed more than 5 minutes after the onset of the chill the chill had an average duration of 9.7 minutes. In some cases relief is almost instantaneous. Most of the cases treated were *P. vivax* infections; there were however 3 *P. falciparum* and 4 mixed infections. All responded equally well.

In the 50 trials 14 patients complained of untoward effects: nausea and vomiting 4, headache 6, oppression over the chest 1, epigastric discomfort 1, flushing of the face 1, dizziness 1. None of these symptoms was severe enough to suggest that calcium gluconate should not have been given.

The precautions recommended are: careful venipuncture to avoid extravasation of calcium solution into subcutaneous tissue, which might cause necrosis; slow injection; the patient should be recumbent for 15 minutes after the injection. Intravenous calcium is contraindicated in cardiac cases, particularly those with arrhythmias and bradycardia and in patients receiving digitalis therapy.

Norman White

MORRIS, W. Zur Behandlung der Malaria tertiana mit intravenösen Gaben von *Tartarus stibiatus*. [The Treatment of Benign Tertian Malaria by Intravenous Doses of Antimony Tartrate.] *Dtsch. Tropenmed. Ztschr.* 1944 Apr.-May v. 48 Nos. 7/10 169-76 2 figs. [18 refs.]

The author reports the use of intravenous antimony tartrate in four cases of inoculated benign tertian malaria. This treatment has no advantage over atabrin in the acute malarial attack but may be indicated in relapses occurring very soon after curative treatment. Combined therapy may assist erythropoiesis. The X-ray shadows of both spleen and liver are intensified under antimony treatment.

ORATION, A. C., Jr. A Short-Term Chronic Toxicity Test employing Mice. *J. Pharm. & Exper. Therap.* 1945 Oct. v. 85 No. 2, 111-18, 3 figs.

In the preliminary testing of antimalarials it was necessary to carry out chronic toxicity determinations on the more active new substances. For this purpose the drugs were incorporated in the diet of mice and to meet possible criticisms of this method it was shown by experiment that the results differed in no essential respects from those obtained through giving the drugs by stomach tube. The mouse has certain advantages over the rat as an experimental animal, in that drug-diets can be quantitatively administered, less drug is required per animal, and the intake of the mouse is, in general, more satisfactory. In this communication, the method of administering drug-diets to groups of 10 mice for a period of 7 days is described. Valuable information was obtained by this means regarding the toxicity of these substances in man. A simple type of cage with feeding arrangements was used, in which each animal was housed individually. Sufficient diet was prepared for each group of mice using starch as excipient for the drug before incorporation with the main diet in different concentrations. Mice weighing around 16 gm. were found most satisfactory

and in practice the total weight of a group was used for assessment of results. The animals not excessively hungry when the experiment started, were kept on a schedule of light and dark, 3 hours of each alternately, and the drug was therefore administered in a manner resembling that employed in human malaria where several daily doses are usually given. The amount of diet consumed, day of death and other relevant data were recorded. Many factors had to be considered in interpreting the results. Death of the animal proved the most reliable guide in evaluating the toxicity of large numbers of compounds. The mean daily drug intake which allowed the survival of 9 out of 10 mice over the experimental period was selected as the objective régime of diet and they generally indicated a different value for toxicity from that based on death as the end point. In each experiment a suitable compound was chosen as a reference standard for toxicity. The value of the method may be judged by the fact that quinaquine [mepacrine] hydrochloride was found to be four times as toxic and pamaquin hydriodide 14 times as toxic as quinine hydrochloride.

RIBBANDS C R The Use of DDT as a Mosquito Larvicide on Still Waters
Bull Entom Res 1945 Nov 36 Pt. 3 315-30

The effect of DDT both in oil solution and as a dust was tried in a number of artificial breeding pits 4 ft x 3 ft. filled naturally with seepage water and containing larvae of *Anopheles culicifacies*, *A. vagus*, *A. barbrostris* with a few *A. hyrcanus* and *A. subpictus*. Preliminary control trials showed that oil itself at a dose of 4 pmts per acre had no deleterious effect on larvae and twice this amount produced a reduction which was not necessarily significant. Five per cent DDT in oil at doses of one third and one-half pint per acre caused 90 per cent. mortality of anopheline larvae and doses over one pint consistently caused 100 per cent. mortality in 24 hours. Malariaol kerosene and waste engine oil were used as solvents and it was found that the vehicle made no appreciable difference to the efficiency of the DDT. It does not kill eggs hence young larvae may hatch out soon after treatment with heavy doses a fact which may obscure the residual action if all larvae are counted a better guide to effectiveness being the presence of 2nd to 4th instar larvae. Using this as a criterion doses of 2 gallons of 5 per cent solution per acre give complete control for 11 days 30 per cent control up to the 18th day and some degree of control up to a month whereas oil itself is completely ineffective by the eleventh day.

A series of trials was made in natural waters with the object of determining the average distance through which small quantities of DDT in waste engine oil would spread and exert a lethal effect when applied at a single point. Small quantities of oil solutions were applied by means of a pipette at the edge of breeding places and the extent of the perimeter sterilized of larvae was measured. Some of the results being summarized below.

From these results it is concluded that DDT solutions are lethal in the stable and far reaching monomolecular films which are the final end of all oil solutions on a water surface. The application of these conclusions was checked by controlling breeding in a marsh by the distribution of DDT oil solution cast in 5 cc. doses at intervals of 12 ft around the perimeter the use of very simple apparatus is recommended. [These observations on the spread of DDT solutions are of considerable practical value for they indicate that there is no need for spraying apparatus more complicated than an oil-can or a drop bottle. It is unfortunate that the use of a trade-name the R.W. oil squirt, tends complication to a paper which otherwise goes far to simplify technique.]

TABLE V.

DEONIER, C. C & BURRELL, R. W. Airplane Application of DDT Larvicides.
J Econom Entom 1945 Aug v 38 No. 4 425-7

The application of DDT as a dust from aircraft presents several technical difficulties and is not a certain means of killing mosquito larvae. The application of solutions or emulsions by this means however is a very promising method of mosquito control. Less weight of material need be carried than when Paris green is being applied, the droplet size can be regulated, low flying is not necessary and the method is convenient. Preliminary tests gave kills varying from 94.9 per cent. to 100 per cent. in vegetated marshes and 100 per cent. in open water. Further studies are in progress.

HAWKING F. Growth of Protozoa in Tissue Culture. I. *Plasmodium gallinaceum* Exoerythrocytic Forms. *Trans Roy Soc. Trop Med & Hyg* 1945 Dec., v 39 No. 3 245-63 29 figs. [12 refs.]

The paper describes the author's attempts to cultivate *Plasmodium gallinaceum* *in vitro*. He had little success with the erythrocytic stages. The utmost was a survival of parasites for five days as proved by injection of clean chicks. The inoculation of chick embryos was carried out by various methods on 69 eggs. In most cases the embryos died, but on 14 occasions chicks hatched. In no case were malarial parasites present in the blood at the time of hatching but in three they appeared in 10 to 14 days. As noted by the author in his preliminary paper [this *Bulletin* 1944 v 41 732] striking results were obtained with exoerythrocytic stages grown in cultures of macrophages and related cells. The tissue cultures were set up in Carrel flasks to the bottom of which four to six cover glasses were fixed by means of fowl plasma. On each cover glass a drop of plasma is placed and a small portion of the tissue to be cultivated usually the spleen is introduced into this plasma by means of a pipette which also serves

for the removal of excess of plasma. When the plasma has coagulated and the embedded tissue is fixed to the cover glass the fluid medium (Tyrode's solution) is added. The cultures are incubated at 37°C.

When the cultures were started from the tissues of chicks previously inoculated with sporozoites of *P. gallinaceum* developmental forms of this parasite appeared in the macrophages and other cells. These were detected by removing one of the cover glasses and examining it microscopically after fixing and staining the growing cells and parasites on its surface. Positive cultures have been obtained from the spleen bone marrow buffy coat of centrifuged blood and liver. In spite of its heavy content of exoerythrocytic forms the brain failed to yield a positive culture. In any positive culture parasites in all stages of development are present at the same time—forms with one, two, four and more nuclei (up to 50 or more) within the cytoplasm of the cells. Extracellularly merozoites may be detected. These have a central nucleus and are rounded at one end and pointed at the other. Toward the rounded end a granule of volutin is often present. Usually the cultures were made from the tissues of the chicks or 8 days after the inoculation of sporozoites. Positive cultures have however been made before this the earliest being one hour after the inoculation of sporozoites. In some instances tissue cultures started from the spleen of an uninfected chick have been infected by introducing parasites from a positive culture but attempts at further passage were not successful. The viability of the parasites in cultures was tested by inoculation of chicks. The oldest culture which proved infective was one at its 89th day. Microscopically parasites were detected in cultures up to 61 days but with increasing age more degenerating cells and parasites occur. Attempts to commence cultures by introducing sporozoites into tissue cultures were not successful nor was it possible to infect erythrocytes by introducing these to cultures. In general the development of *P. gallinaceum* in cultures corresponds very closely with the course of development of the parasite in chicks following sporozoite inoculation. The paper is illustrated by photomicrographs and by a series of black and white drawings of the various stages described.

BRACKETT S. WALETZKY E. & BAKER Margaret. The Rate of Action of Sulfadiazine and Quinine on the Malarial Parasite *Plasmodium gallinaceum*. *J. Pharm. & Exper. Therap.* 1945 July v 84 No 3 254-61 2 figs [13 refs.]

It is agreed that sulphonamides generally exert their full inhibitory effect on bacteria only after a time lag and similar observations have been made in regard to malarial parasites. The authors suggest that in general the rate of action of these drugs may vary inversely with the rate of growth and reproduction of the organism in question. They have tested their view in the case of the relatively slow growing protozoan *P. gallinaceum* by comparing the results of treatment of this infection in chickens with quinine which acts quickly with those following treatment with sulphadiazine or a derivative. Two experiments with similar results were made in which 15 one week-old chicks were inoculated intravenously with a homogeneous suspension of small forms of the parasite from a donor bird, two days after drug administration had begun. Five of the chickens received a diet containing 0.2 per cent. of sulphadiazine five others received quinine in similar amount and the remaining five served as controls. The resulting blood level of sulphadiazine was well above that giving maximum activity in this infection. The course of the infection was followed by making parasite counts immediately after inoculation and 12 hourly thereafter. Differential counts of the parasites were also made in four groups according to size as a guide to the effect of each drug on growth and reproduction. It was

May 1946

found that sulphadiazine inhibited growth only after 24 hours, whereas the effect of quinine was very rapid. Treatment of the first generation with the former drug caused a reduction in the number of meronts but segmentation was completed and new red cells were invaded without the succeeding development going beyond the four-nucleate stage. The maximum number of parasites was present on the second day of treatment and then gradually declined, whereas in the case of quinine there was no increase of the original numbers. Morphological changes in the parasites occurred more quickly with quinine than with sulphadiazine. In a further experiment with sulphadiazine and its bromo-derivative action against erythrocytic and exoerythrocytic forms in sporozoite-induced infections was also slow.

The view of the authors that the time required to cause effective inhibition by slow-acting drugs like the sulphonamides, increases in proportion with the slowness of the rate of growth of the organism, appears to be confirmed, and may be of practical significance in chemotherapy.

ZUCKERMAN A. In Vitro Tests with *Plasmodium gallinaceum* and *Plasmodium lophurae*. *J Infect Dis.* 1945 July Aug v 77 No. 1 23-39 4 graphs & 1 pl. 33 refs.

Having devised a technique for growing macrophages *in vitro* from the blood agranulocytes of chickens, their phagocytic powers against pneumococci in the presence or absence of antipneumococcus opsonic serum was tested. It was found that many pneumococci were phagocytized by the macrophages in the presence of 1:1000 diluted serum, but that phagocytosis was negligible in the absence of immune serum. In addition to being phagocytized, the pneumococci were agglutinated and became adherent to the macrophages. Having demonstrated that opsonization occurred in the case of bacteria, the test was applied to malarial parasites (*P. gallinaceum* and *P. lophurae*) in chickens. It was found that phagocytosis of infected red cells occurred in the presence of hyperimmune homologous serum, but not in the presence of normal chicken serum or of serum from chickens which had merely recovered from an acute initial infection. In addition, as in the case of the bacteria, there was agglutination of the infected cells and their adhesion to the macrophages and to the surface of the glass. These various phenomena involved not only infected cells but also uninfected cells, and are responsible for stimulating phagocytosis in the case of *P. gallinaceum* was more readily absorbed by normal than by infected blood corpuscles, an observation which suggests that the absorbing material is a constituent of the normal red blood corpuscles. There was some evidence that opsonization occurred not only *in vitro* but also *in vivo* for the phagocytic index in the presence of normal serum was higher when the parasitized red cells were collected at the time of the crisis than when they were collected before or after this event. This is a long paper describing in detail the method of cultivating the macrophages and the various procedures which have to be carried out in order to obtain the data for calculation of the opsonic indices. The appearances of phagocytosis and adhesion are illustrated in a plate of 13 figures.

SEILER, A. O & OTT, W. H. Studies on Nutrition and Avian Malaria. III.—Deficiency of "Folic Acid" and other Unidentified Factors. *J Infect. Dis.* 1945 July-Aug., v 77 No. 1 82-4

It is shown that *P. lophurae* infections, as judged by parasite counts are more severe in chicks on a diet deficient in "folic" acid and other unidentified

factors than in those on an adequate diet. The chicks on the adequate diet weighed 150 gm. at three weeks whereas those on the deficient diet weighed only 100 gm. The continued passage of the strain of parasite through chicks on the deficient diet did not lead to any enhanced virulence for whenever the strain was inoculated to chicks on adequate diet it behaved as did the control strain kept in serial passages in chicks on adequate diet. It seems evident that the severity of the infection is directly related to the nutrition of the host.

BRATTON A C Jr Continuous Intravenous Chemotherapy of *Plasmodium lophurae* Infection in Ducks. *J Pharm & Exper Therap* 1945 Oct. v 85 No 2 103-10 1 fig

A method has been devised to avoid the difficulties which occur owing to incomplete absorption and possible degradation of drugs in the alimentary canal of ducks when assessing the value of antimalarials administered to them by mouth. It consists in giving a continuous intravenous infusion of a solution of the substance under test over a period of three days. By this means precision in dosage can be attained and a new method of studying certain problems in chemotherapy is made available. White Pekin ducks infected with *P. lophurae* were used. In order to limit loss of body weight during the test an average of 250 cc. of infusion fluid per kgm. body weight per day was required. The infusion also served to maintain water balance and nutrition as ducks cannot retain food in the normal way under the conditions of the test. With larger volumes of fluid than the above the ducks became oedematous. Details of the method regarding choice of ducks, immobilization of the birds and construction of the pump used should be consulted in the original. Briefly after immobilization a 22-gauge needle is inserted into the leg vein of a duck and secured. It is connected to an individual pump, six of which are fitted to a common shaft which makes 7 revolutions per hour. The pumping action is effected by two rollers mounted opposite one another which compress a rubber tube between them and expel its contents through an outlet while behind them it is refilled from an inlet and a continuous flow of fluid can be maintained. The mechanism proved simple and dependable. The drug was dissolved under sterile conditions in an isotonic solution containing 1.2 per cent. of sodium citrate and 4.2 per cent. of glucose adjusted to pH 7 by hydrochloric acid. One bird in each series received infusion without drug and the concentration of the latter for the other birds was calculated after consideration of all the factors. Each bird was infected intravenously from a donor bird with a dose of 3×10^9 parasitized cells per kgm. body weight. Parasite counts and other relevant data were made daily. The minimum effective dose of a drug is defined as that necessary to reduce the number of parasites in a treated bird to half that in a control bird, on the third day when the experiment ended. The following is the author's summary —

- 1 A method incorporating a simple rotary injection pump is described for continuous intravenous administration of drugs to ducks infected with *P. lophurae*.
- 2 On the basis of dosage quinine was more effective at the level of minimum therapeutic response when given intravenously in single daily doses than when given by continuous infusion at a high level of response the converse was true.
- 3 At the level of minimum response cinchonine was equally effective when given in single daily intravenous doses or continuously.
- 4 Tartar emetic, sodium antimony thioglycollate and mapharsen were effective in doses at or near the toxic level.

5 Penicillin streptomycin, and quinine were inactive in the doses employed.

6. Summation of therapeutic response was shown by the following two combinations quinine-cinchonine, and quinaquine-8-chloro-9-(2-diethylamino-ethylamino)-2-methoxyacridine. No summation of response was exhibited by the following combinations quinine-quinaquine quinine-pamaquine and quinaquine-pamaquine. These results suggest that quinine quinaquine and pamaquine each possess a different principal mechanism of drug action against *P. lophurae* in the duck.

TALIAFERRO W. H. Immunity in Malaria. *Amer J Clin. Path.* 1944 Dec., v 14 No 12, 593-7 [23 refs.]

This is an interesting article which might be entitled "An Introduction to the study of Immunity in Malaria." It reviews the knowledge which has been acquired chiefly from the study of the course of infections of *Plasmodium brasilianum*, a quartan parasite of New World monkeys in which the author has played a prominent part.

In the first place the infection increases acutely in intensity till as many as 10 per cent. of the red blood corpuscles are infected. This acute rise is terminated by a parasite decline at times so sudden as to justify the application of the term crisis. This is followed by a low-grade infection and finally by latency when no parasites can be found in thick blood films. This latency is interrupted by frequent relapses of varying severity as occurs with all quartan parasites. In man *P. vivax* has a similar course but the relapses are less frequent than with *P. malariae*. In the case of *P. knowlesi* in rhesus monkeys however the infection develops rapidly during the course of a week till as many as 80 per cent. of the red cells are infected, a result which is nearly always fatal. Occasionally there is a terminal reduction in the number of parasites but this is insufficient to ward off the fatal issue. By treatment however the infection can be reduced so that a condition of low-grade infection, or latency is reached. In many respects *P. knowlesi* though of tertian periodicity resembles *P. falciparum* in man.

Natural immunity to *P. brasilianum* is exemplified by the fact that in first infections 6 to 8 of the 9 merozoites produced at each schizogony are destroyed before red cells are invaded and of those that succeed in establishing themselves half fail to become mature schizonts. This rate of destruction, which is largely a phagocytic phenomenon is greatly increased when there is an acquired immunity. The destruction of the parasites is correlated with the phagocytosis of free parasites and infected red corpuscles chiefly in the spleen liver and bone marrow. This is particularly marked in the spleen where filtration of infected cells occurs in the Billroth cords as the result of the action of a specific agglutinin. This is followed by opsonization which stimulates phagocytosis. In *P. falciparum* infections the infected cells are often agglutinated in other organs for instance in the brain or placenta with the result that the phagocytic cells the macrophages become active in these unusual sites. The most reasonable explanation of the increased activity of macrophages in acquired immunity is that they and the parasites are influenced by a specific opsonin. It has been shown by COGGERHALL and KUMAR (this Bulletin 1938 v 35 109) that acquired immunity to *P. knowlesi* can be passively transferred with immune serum. In addition to the development of antibodies during acquired immunity certain non-specific factors operate. There is a tremendous hyperplasia of macrophages and lymphoid cells chiefly in the spleen and bone marrow. These new macrophages arise from division of pre-existing macrophages or from lymphocytes and monocytes.

The results obtained in the study of monkey malaria have their parallel in human malaria. Certain races have a higher natural immunity than others while acquired immunity has been clearly demonstrated in man under experimental conditions. Absolute immunity is difficult to acquire because the immunity is strain-specific. The largest number of strains is found in *P. vivax* and the smallest number in *P. malariae*. In any case when there is an acquired immunity this is largely if not entirely associated with a latent or low grade infection which is liable to relapse at any time. Attempts have been made to induce artificial immunization passively or actively in monkeys and birds with some success but this procedure offers little promise in man. On the other hand, though there is little to suggest that artificial immunity can be employed to protect man there is little doubt that it is an adjuvant in drug treatment. The mechanism of relapse is not known though there is an increasing tendency to ascribe this to the persistence during latency of exoerythrocytic stages. These lead to infection of erythrocytes which are destroyed so long as immunity persists. When this immunity subsides the erythrocytic development progresses unhindered, sometimes with serious results.

Other serological changes occur during malarial infections. Thus antibodies including precipitins agglutinins and complement-fixing substances are produced. From the immunological standpoint it is of interest that complement fixation depends on a genus antigen and is thus very different from acquired immunity which is species and strain specific. Thus effective complement-fixing antigens for human malaria have been prepared from *P. knowlesi* and *P. gallinaceum*. The various points mentioned in this summary in their bearing on the epidemiology treatment and control of malaria are discussed in the paper which is rendered all the more valuable by the author's careful reference to the original papers upon which his statements are based. BLACKWATER FEVER.

KITCHEN S F & SADLER G G Report of an Attack of Blackwater Fever subsequent to Induced Malaria. *Amer J Trop Med* 1945 Sept. v 25 No 5 379-84 3 figs.

The authors describe in detail the occurrence of blackwater fever in a female patient in whom malaria was induced by the introduction of three plasmodial species in succession viz. *P. vivax*, *P. falciparum* and *P. malariae*. The *P. vivax* infection was characterized by 27 quotidian paroxysms and spontaneous termination. Occasional parasites were seen in the peripheral blood several months later but without clinical signs of malaria. Six months after the termination of the *P. vivax* attacks a natural inoculation of *P. falciparum* was given. The resulting malaria was treated with quinine. Five weeks later *P. malariae* infection was induced by intravenous injections of infected blood. This infection was terminated by plasmoquin six weeks later *P. falciparum* persisted in the peripheral blood in spite of these treatments. There were waves of parasitaemia with only occasional clinical signs of malaria, for nearly five months. At the end of this period the patient was given two seven-grain doses of quinine in a single day, the last dose being given at 6 p.m. She refused her evening meal and vomited in the early morning. At 7 a.m. it was noticed that she was jaundiced, and by noon her temperature had reached 103°F

"Late that afternoon" she passed urine containing haemoglobin. There was no rigor associated with the haemoglobinuria. Thereafter the clinical condition was that of typical blackwater fever and rigors were experienced on the sixth and seventh days. There was no oliguria. The urine during the lytic phase was characteristic in appearance. The reaction is not given. She had only one lytic phase and recovered rapidly. *P. falciparum* was not observed in the blood from the onset until the third day after the subsidence of the fever. Treatment included infusions of 5 per cent glucose in physiological saline, and 50 per cent glucose from the first day. Transfusions of 500 cc. of citrated blood were given on the first, second, fourth and seventh days. The red blood cell count was 0.89 million per cubic mm. on the first day and rose to 1.2 million per cubic mm. on the seventh day. The intake of fluid was carefully balanced throughout against the output in the urine. Sodium bicarbonate was given by mouth in doses of 1 gm. every four hours on the first day.

The chief interest of this case lies in the malarial history. All these strains were well known and had frequently been used for therapeutic purposes. None had any previous record of having been associated with haemoglobinuria.

The authors suggest that the prolonged parasitaemia resulting from the *P. falciparum* malaria may have been an aetiological factor in the production of the haemoglobinuria. They also point out the relationship of quinine administration to the haemoglobinuria attack, as the clinical history of the patient indicates that haemolysis commenced within 12 hours of the administration of the first dose of quinine.

They discuss the treatment from the point of view of replacement of blood by transfusion (they estimate that about three-quarters of the patient's cells were lysed in less than 24 hours) and the administration of alkali. They consider that the hypothesis that oliguria and anuria are the result of blockage of the renal tubules by haemoglobin degradation products is open to doubt, and conclude that the indiscriminate use of intensive alkaline therapy is contra-indicated in blackwater fever.

[The legends for Figures 2 and 3 have been accidentally transposed in the printing of this paper.]

B. G. Macgrath

LANCET 1945 Dec 1 701-4 1 chart. [23 refs.] Effect of Large Doses of Alkali on Kidney Function. [Army Malaria Research Unit, Oxford (Macgrath B. G. et al.)]

Intensive alkali treatment is still being recommended for the treatment of blackwater fever incompatible blood transfusion and the crush syndrome. The Medical Research Council recommended that in the treatment of wound shock all cases should be given sodium bicarbonate 7 gm. (about 2 drachms) hourly by mouth until the urine turns red litmus blue but not for longer than 24 hours. Intensive alkali therapy of this kind is accompanied by dangers. Experiments described in this paper show that alkali administered for 24 hours to normal subjects at less than half the rate recommended above produces sodium and water retention and disturbance of renal function, which becomes well-marked if the alkali is continued for 72 hours.

Three subjects were given sodium bicarbonate, grams 60 and sodium citrate grains 60 3-hourly, one subject for one day, two for three days. All had disturbance of renal function in one on the 3-day course this was well marked and led to a three-fold increase of blood urea. All developed sodium and water retention. There was dilution of the blood by about 10 per cent.

The authors consider that large doses of alkali should not be administered in conditions where renal failure may supervene.

Norman White

- i. OSMAN A. A. Effect of Large Doses of Alkali on Kidney Function. [Correspondence.] *Lancet* 1946 Jan 26 143-4
- ii. LOCKET S. Effect of Large Doses of Alkali on Kidney Function. [Correspondence.] *Ibid* Feb 2 180-81

i. OSMAN considers the conclusion of the Malaria Research Unit Oxford that large doses of alkali should not be administered in conditions where renal failure may supervene to be an overstatement. A closely reasoned argument ends thus. Alkali therapy in renal disease certainly has limitations. It is contra-indicated in the earlier stages of acute nephritis for example, but I have generally found that when failure with this method is attributed to its unsuitability it is as often due to faulty technique. I submit that large doses of alkali, when properly used are not necessarily contra indicated in conditions where renal failure may supervene as a natural development of the disease but that given with caution they will sometimes be the only means of saving or prolonging life.

ii. LOCKET considers the findings of the Malaria Research Unit Oxford to be insufficient to justify the conclusions based thereon. The title of their paper is somewhat misleading as only sodium salts were investigated potassium and other alkaline salts were not considered. He does not consider the evidence adduced sufficient to justify the deduction that renal function was impaired in the three experimental subjects

TRYPANOSOMIASIS

STEFANOPOULO G CAUBET P & DUVOLON S Mlle Méningoencéphalite à *Trypanosoma gambiense* (souche neurotrope) observée chez le lapin. [Meningo-Encephalitis due to *T. gambiense* in the Rabbit.] *Bull Soc Path Exot* 1945 v 38 Nos. 9/10 271-4 4 figs. on 2 pls

The Yaunde strain [this *Bulletin* 1946 v 43 312] of *Trypanosoma gambiense* in the blood of a rat was injected subcutaneously into the same rabbit on June 1 1943 October 19 1943 November 3 1943 and November 20 1943 during observation for a year the rabbit showed no signs of illness and its weight remained about the same. On June 30 1944 paralysis of the hind quarters developed and soon extended to the forelimbs the rabbit was killed on July 5 1944

At autopsy the spleen was found to be rather small the urinary bladder was distended with 160 cc. of urine and the membranes of the brain were much congested. No trypanosomes were seen in fresh blood preparations but they were present in lymphatic gland juice and especially in scrapings of brain tissue in saline. The cerebral membranes showed pachymeningitis with infiltration of lymphocytes and plasmocytes perivascular cellular infiltration was seen in the brain. In sections trypanosomes were fairly numerous in the infiltrated areas of the membranes and some isolated trypanosomes were present in the brain tissue. The general appearance was similar to what is found in sleeping sickness in man. No morular cells of Mott were seen in the brain but a few were present in the spleen. These findings are shown in photomicrographs.

The authors comment that the neurotropic character of this strain shown in the mouse and rat is also apparent in the rabbit

Tropical Diseases Bulletin

ROUBAUD E. & CAUBET P. Essais d'immunisation chimio-biologique par le sulphasénol dans les infections à *Trypanosoma gambiense* chez le rat. [Attempts at Chemo-biological Immunisation in Infections with *Trypanosoma gambiense* in the Rat.] Bull. Soc. Path. Exot. 1944 v 37 Nos. 8/10 280-84

Two laboratory strains called Antwerp and Yaounde respectively [see CAUBET this Bulletin 1946 v 43 312] were used and five experiments were made. The object was to see whether rats developed immunity after treatment of *T. gambiense* infections with sulphasénol and, if so to estimate the degree and specificity of the immunity. The rats were infected by intra peritoneal or subcutaneous inoculation, and sulphasénol was injected as soon as trypanosomes were found in the peripheral blood. After varying intervals the immunity was tested by inoculation of one or other of the two strains of *T. gambiense* and also in one experiment by injection of *T. evansi*. The doses of sulphasénol are expressed as per 100 gm body weight.

Experiment 1—Five white rats were inoculated with the Antwerp strain trypanosomes appeared after 48 hours and 0.03 gm. of sulphasénol was injected and sterilized the peripheral blood. After 70 days interval, 15 000 trypanosomes of the Antwerp strain were inoculated intraperitoneally two untreated rats and two others which had been injected with the same dose of trypanosomes. The untreated controls received, as controls the same dose of trypanosomes. The untreated controls showed trypanosomes on the 4th day and these were numerous on the 10th day. The control which received sulphasénol 70 days before behaved similarly while the control which had received the drug 20 days before was not infected. Of the 5 experimental rats, two behaved like the untreated controls while the other 3 developed a slow irregular infection which did not become acute until 13 to 20 days later than in the controls.

Experiment 2—Three experimental rats and 2 untreated control rats were used. The same procedure as in the first experiment was carried out but the interval was 80 days and the test dose was 500 trypanosomes. The 3 rats became infected but much more slowly than the controls.

Experiment 3—A rat of experiment 1 [2?] infected with the Antwerp strain in spite of treatment with 0.03 gm. of sulphasénol 80 days before, was given a second injection of 0.01 gm. of sulphasénol to reinforce its immunity after 40 days. 200 trypanosomes of the Antwerp strain were injected. Trypanosomes appeared in the blood on the 5th day but the infection was chronic, with few trypanosomes in the blood and the rat died on the 80th day whereas the control rat died of an acute infection on the 60th day.

Experiment 4—Two rats infected with the Antwerp strain and sterilized by an injection of 0.015 gm. of sulphasénol were tested after 80 days with a dose of 400 trypanosomes of the Yaounde strain injected subcutaneously. 2 untreated rats serving as controls. The controls showed trypanosomes on the 12th and 25th days respectively and the former died with an acute infection after a month. The experimental rats showed trypanosomes on the 23rd and 41st days respectively and the latter died on the 60th day [the times of death of the other control rat and the other experimental rat are not stated].

Experiment 5—Two rats were injected with 0.03 gm. of sulphasénol and 75 and 80 days later [75 & 80 jours] were infected with the Antwerp strain. They then received a second injection of 0.014 gm. of sulphasénol, one 10 days and the other 30 days after the appearance of the trypanosomes. Finally they were inoculated with 1,000 trypanosomes of *T. evansi* one after 30 days and the other after 80 days, two untreated control rats being also injected. All four

animals responded similarly they showed trypanosomes at 5 to 8 days and died at 11 to 12 days

The authors remark that the protection was relative only and was apparently specific for *T. gambiense* even though the two strains showed pathogenic differences. There were indications that the destruction of trypanosomes in the tests with injection of 15 000 produced some toxæmia. [It seems to the abstracter that more rats might have been used with advantage.]

ROUBAUD E. A propos des caractéristiques raciales des souches de *Trypanosoma gambiense* [Racial Characters of Strains of *Trypanosoma gambiense*] *Bull Soc Path Exot* 1944 v 37 Nos 9/10 290-91

The author refers to CAUBET's measurements of two strains of *T. gambiense* [see this *Bulletin* 1946 v 43 312] and asks whether such different strains exist in nature or are artificially produced by long maintenance in laboratory animals. The characters of the Yaunde strain have never varied since its isolation and it has never become completely adapted to the blood of small rodents: this suggests that it is a special racial type with marked neurotropic characters [see below]

Perhaps a selection occurs in man when the infection passes from the early stage in the blood and lymphatic glands to the later stage with involvement of the central nervous system: these selected races might be spread by tsetse flies in nature. This could explain the variations between the clinical picture and the number of cases [*gravité relative de l'endémie*] often observed in sleeping sickness areas. KUNERT [this *Bulletin* 1940 v 37 17] noted earlier infection than formerly of the nervous system in *T. rhodesiense* infections in man and Roubaud suggests that this might be explained by the predominance of neurotropic strains: since in such infections trypanosomes are rare in the peripheral blood the infection would be less transmitted by tsetse with the result that the amount of sleeping sickness in the area would diminish while the virulence for the nervous system would increase. The question deserves attentive study.

ROUBAUD E. STEFANOPOULO G J & DUVOLAN S. Mlle. Étude chez le rat blanc d'une souche neurotrophe de *Trypanosoma gambiense* [A Study of a Neurotropic Strain of *T. gambiense* in the White Rat.] *Bull Soc Path Exot* 1944 v 37 Nos 9/10 292-6 3 figs (2 on 1 pl.) [10 refs.]

During 1943 twelve white rats were infected from guinea-pigs, mice or other rats with the Yaunde strain of *T. gambiense*. Three died of the disease after 31, 37 and 54 days and six were killed after 55, 66, 68, 77, 77 and 82 days. The incubation period varied from 4 to 45 days. In the blood the trypanosomes were few and were often absent and in only three rats were trypanosomes very numerous at the time of death. In several rats trypanosomes were found at autopsy only in the central nervous system and in some in the lymphatic glands also. Two rats were inoculated intracerebrally and both became paralysed and were killed after 79 days: one only had shown trypanosomes (very few) in the blood on the 17th and 74th days but they were very numerous in the brain in both rats. In most cases there was little fever. The body weight remained stationary except in young rats where slight increase occurred and in infections of long duration where marked wasting took place. Four out of 5 rats in which the infection had lasted for more than two months showed severe nervous symptoms—tremors, staggering, spasms or contractures, paresis or paralysis of the limbs or sphincters.

At autopsy the spleen usually showed little enlargement but the lymphatic glands were very often hypertrophied and sometimes congested. The histological appearances of most interest were in the central nervous system. 7 out of 11 rats showed meningoencephalitis similar to that described in the mouse by STEFANOPOULO and ÉRÉVÉ [this *Bulletin* 1945 v 42, 258]. This was seen especially in rats killed after the 60th day. There was intense perivascular infiltration chiefly of plasmocytes, the neurones frequently showed damage and neuronophagia was observed, especially in the two rats which were inoculated intracerebrally. Trypanosomes were seen in the brain substance in three cases. In one of those inoculated intraperitoneally which was killed on the 68th day the blood showed a few trypanosomes but on the 33rd day only. The other organs showed the usual lesions such as infiltration of the portal canals of the liver, necrosis and degeneration of some hepatic cells, interstitial infiltration of the kidney, many plasmocytes in the spleen &c. [the heart is not mentioned]. The mulberry cells of Mott were seen in the brain and spleen of some of the rats [see below].

For comparison 12 rats were similarly inoculated with the Antwerp strain [see CAUBET this *Bulletin* 1946 v 43, 312] which produced acute infections. In only one of 7 rats examined were there lesions of meningo-encephalitis.

The authors refer to the work of others [see this *Bulletin* 1945 v 42, 258] they regard the Yaunde strain as a race of *T. gambiense* with certain fixed characteristics. J. F. Corson

JACKSON C. H. N. Pairing of *Glossina morsitans* Westwood with *G. swynnertoni* Austen (Diptera). *Proc. Roy. Entom. Soc. London*. Ser. A. Gen. Entom. 1945 Dec 31 v 20 Pts 10-12, 108.

It is already known that in cages males of *Glossina morsitans* or *swynnertoni* mate at random with females of either species and do not select those which are co-specific.

The author has carried out a field experiment to examine the same point. He worked in a spot in which *G. swynnertoni* was abundant and exposed large numbers of pupae of both species in such a way that the adults on emergence were completely free. He caught several hundred pairs and studied the proportion in which the two individuals were of the same or different species. He concludes that even in nature male *G. swynnertoni* mates at random with females of its own species or *morsitans*. The same is probably true of male *G. morsitans* but the numbers were lower and the result not conclusive.

This is remarkable for it has been shown by VANDERPLANK [this *Bulletin* 1945 v 42, 99] that heterogamous matings are barren or nearly so, yet neither species has any mechanism to prevent this occurrence. P. A. Burton.

STEFANOPOULO G. CAUBET P. & DUVOLOX S. Mlle. Présence de cellules mulberry-formes de Mott chez les rats infectés de *Trypanosoma gambiense*. [The Mulberry Cells of Mott in Rats Infected with *Trypanosoma gambiense*] *Bull. Soc. Path. Exot.* 1944 v 37 Nos 9/10 296-300 4 figs on 1 pl. [17 refs.]

The "mulberry cells" of Mott were found in the tissues of 2 out of 11 white rats infected with the Yaunde strain of *T. gambiense*. In one rat they were present in the splenic pulp amid numerous plasmocytes. In some mulberry cells the nucleus had disappeared but in others the plasmocyte character of the cell was recognizable, i.e. eccentric nucleus radiating spoke-like chromatin and basophilic cytoplasm with vacuoles or globules, polygonal from mutual pressure which stained rose-violet with Giemsa's stain. Many intermediate

forms between the plasmocvte and the typical mulberry cell were seen. In sections of the brain of the second rat there were lesions of meningo-encephalitis intense perivascular infiltration and trypanosomes in the brain tissue. Mott's cells were seen both in the infiltrations and in the brain tissue some were stained a rose colour by Giemsa's stain and others were unstained fuchsin stained them a bright red colour. These cells were also present in the spleen of this rat.

Impression films were made of the organs of 6 other rats similarly infected and mulberry cells were found in two of them in the liver and spleen these cells stained a pale blue a difference from those in sections which was noted by REICHENOW (*Ztschr f Hyg u Infektionskr* 1921 v 94 266). They were also found in impression films of the organs of guinea pigs and mice infected with this strain of *T. gambiense*.

In discussion LAVIER emphasized the value of staining with fuchsin to distinguish Mott's cells from other very similar cells such as macrophages packed with refractive inclusions. He and others who took part in the discussion considered that Mott's cells are not pathognomonic of trypanosomiasis. CAPPONI referred to their presence in *T. lewisi* infections of the brown rat in Marseilles observed by ARGUE and himself in 1943.

EAGLE H. The Spirochaetidal and Trypanocidal Action of Acid-substituted Phenyl Arsenoxides as a Function of pH and Dissociation Constants. *J. Pharm & Exper Therap* 1945 Nov v 85 No 3 265-82 8 figs [24 refs.]

In earlier papers Eagle and his associates described the action of a number of substituted phenyl arsenoxides on spirochaetes (*J. Pharm & Exper Therap* 1940 v 70 221) and trypanosomes [this *Bulletin* 1945 v 42, 15]. With only a few exceptions acid substitution caused a marked decrease in activity of the parent arsenoxide and in the present very interesting contribution Eagle produces considerable evidence for the view that this diminished activity is to be explained on the basis that the ionized salts of these substituted compounds are relatively inactive as compared with the undissociated free acids. This is in line with the facts (a) that the dissociation constants of most of these compounds are such that they would be more than 99 per cent ionized at pH 7.4 and (b) that increase in the hydrogen ion concentration of the medium in which the tests are conducted results in increased spirochaetidal or trypanocidal activity.

With regard to (b) above, the most obvious effect of increasing the hydrogen ion concentration consists in the formation of undissociated free acid from the ionized salt e.g. —

If the inference is correct that the undissociated acid is many times more active than the charged ion there should be a close correlation between the trypanocidal activity of an acid-substituted compound at a given pH and the pK of that compound. The higher the pK (i.e. the weaker the acidic group) and thus the higher the proportion of the undissociated acid at a given pH the greater should be the activity of the compound. This was in fact found by experiment to be the case.

That the striking influence of pH on the trypanocidal and spirochaetidal activity of acid-substituted phenyl arsenoxides is related to the ionization of the acidic group is borne out by a number of other findings. Thus the activity of the unsubstituted phenyl arsenoxide was largely independent of pH. This is also true of the 3-NH₂-4OH phenyl arsenoxide in which neither of the substituents is strongly acidic. Still more significant is the fact that when an acidic group is

blocked as by amide formation (e.g. the β -CONH₂ compound) the trypanocidal activity is no longer dependent on pH.

Although the ionized salts of acid-substituted phenyl arsenoxides in general are considered to exercise a relatively low (but variable) degree of activity it is inferred that in a few exceptional instances (as in the β -(CH₃)₂COOH compound see this *Bulletin* 1945 v 42, 354) the ion is unusually active. This adding to the activity due to the undissociated molecule accounts for the unexpectedly high activity of these particular compounds.

Eagle finds sufficient correspondence between theoretical calculation and observed fact to warrant the conclusion that the relative trypanocidal activity of an acid-substituted phenyl arsenoxide is determined by and is roughly predictable from—(a) the pH of the solution (b) the pK of the compound (c) the trypanocidal activity of the ion. The higher the pK, and the lower the pH the greater will be the observed activity of the compound.

Arsenic estimations established that the relative inactivity of the salts of these compounds reflected the fact that they were bound to the trypanosomes to only a minor degree while the undissociated free acids like all highly active compounds were concentrated as much as three-hundred-fold. Variations in pH affecting the relative proportions of ions and undissociated acid, similarly affected the degree to which a given arsenical was bound by the trypanosomes. In a series of acid-substituted phenyl arsenoxides those with the highest pK values (most readily transformed to the undissociated acid on acidification) are the first to show increased activity and increased affinity for the trypanosomes as the reacting mixture is acidified while those with strongly acidic groups which remain as ions at the lowest pH tested are correspondingly unaffected with respect to both activity and combining affinity.

The author discusses the question whether the undissociated acid-substituted phenyl arsenoxides are so strongly bound to trypanosomes because they have an especial reactivity with cellular constituents such as those containing SH groups. He concludes however that the explanation most probably lies in the fact that the undissociated acids penetrate readily into the interior of the trypanosome cell, whilst the ionized salts are unable to gain admission. He quotes a number of instances from the literature of widely-separated fields of experimental biology in support of the general contention that the ions of weak acids (or bases) pass through cell membranes less readily than the corresponding undissociated molecules. A distinguishing feature of the trypanosome-arsenical system here studied lies in the speed at which and particularly in the degree to which, active non-ionized arsenicals may be concentrated by the trypanosomes. Within ten minutes the arsenic concentration in the organisms may attain a level several hundred times greater than that of the surrounding fluid. This reflects a rapid diffusion of the arsenical into the organisms, followed by its firm combination with cellular constituents. The arsenical is thereby effectively removed from the diffusion equilibrium, permitting its continued diffusion into the cell. In a sense the organisms promote their own death by binding the active (undissociated acid) form of the compound and thus shifting the equilibrium so as to result in the production of yet more of that active form.

CHORLEY J. H. Tsetse Fly Operations. Short Survey of the Operations by Districts for the Year ending December 1943. *Rhodesia Agric J* 1944 v 41 No 6 412-19 [Summary taken from *Rev Applied Entom.* Ser B 1946 Jan. v 34 Pt. 1 15]

There was little improvement in the position as regards trypanosomiasis of cattle in the Chipinga area of the Mafsetter District on the eastern border of

Southern Rhodesia, in 1943. The total number of tsetse-flies caught on the Rhodesian side of the border was 20 comprising 11 males and five females of *Glossina pallidipes* Aust. and three males and one female of *G. brevipalpis* Newst while 15 males and 13 females of the former and one male and two females of the latter were taken in the clearing on the Portuguese side. Extensive additions were made to the main border clearing. Patrols carried out in Portuguese East Africa and on the border farms indicated that *G. morsitans* has not spread much further up the Busi Valley though individuals were caught about one mile from the border. A light infestation of this species was found in the lower Sabi Valley inside Southern Rhodesia during the year and trypanosomiasis caused heavy mortality among cattle in the neighbourhood. It is not anticipated that the Sabi and Lundi Rivers will act as effective barriers to the westward spread of the fly as they carry little water in the dry season. The Portuguese Government has declared a large area in Portuguese East Africa along the border east of the Melsetter district an open area for the destruction of all classes of game. This may have highly beneficial results in the control of *G. morsitans* if intensive shooting operations can be organised. The presence of tsetse on the border in the Vila Gouveia area of Portuguese East Africa opposite Inyanga has been notified.

Satisfactory progress was made in the northern areas infested by *G. morsitans* fly densities over the whole area covered by the operations showing a progressive reduction. No cases of animal trypanosomiasis were recorded from these areas. *G. pallidipes* was found to occur some distance south of its previously known limits in the Sebungwe district. The north-eastern boundary of the area remains heavily infested. Eight more cases of sleeping sickness were recorded from the Urungwe district three foci of the disease being now recognised. The situation in individual districts is briefly reviewed and incidental aspects of tsetse control are discussed.

LAUNOY L. Albuminurie de la trypanosomose experimentale à *T. annamensis* du lapin action des agents trypanocides. I. Action du moranyl employé seul. [The Action of Trypanocidal Agents on the Albuminuria of Experimental Infection with *Trypanosoma annamense* in the Rabbit. L. The Action of Moranyl alone] Bull Soc Path Exot 1944 v 37 Nos. 11/12 347-58 4 graphs

Different opinions have been expressed on the importance of the albuminuria which often occurs during the treatment of human trypanosomiasis with Bayer 205 as the author could always cause albuminuria in rabbits by infecting them with his strain of *T. annamense* he decided to make experiments to get an answer to two questions (1) Can moranyl [Bayer 205] cause albuminuria in a rabbit with healthy kidneys? (2) what effect has treatment with moranyl on the albuminuria of trypanosomiasis?

He first injected various amounts of moranyl at various intervals into rabbits (4) and estimated the albumin urea and chlorides in the urine. slight albuminuria was produced but it soon disappeared. He then infected rabbits (3) with *T. annamense* and treated them with moranyl. This cured the infection and the albuminuria also disappeared. The figures of the excretion of urea and chlorides gave no indication of serious damage to the kidney having been produced. Details of the experiments are given.

The author concluded that a single dose of 0.02 to 0.05 gm. (even 0.1 gm.) per kgm. does not cause albuminuria and that doses of 1 to 5 days have little toxic effect on the kidney. slight albuminuria oliguria and hypochloruria are produced. With an interval of 14 days between injections even doses of 0.1 gm.

blocked, as by amide formation (e.g. the β -CONH₂ compound) the trypanocidal activity is no longer dependent on pH.

Although the ionized salts of acid-substituted phenyl arsenoxides in general are considered to exercise a relatively low (but variable) degree of activity it is inferred that in a few exceptional instances (as in the β -(CH₂)₃COOH compound see this *Bulletin* 1945 v 42, 334) the ion is unusually active. This adding to the activity due to the undissociated molecule, accounts for the unexpectedly high activity of these particular compounds.

Eagle finds sufficient correspondence between theoretical calculation and observed fact to warrant the conclusion that the relative trypanocidal activity of an acid-substituted phenyl arsenoxide is determined by and is roughly predictable from—(a) the pH of the solution (b) the pK of the compound (c) the trypanocidal activity of the ion. CHORLEY J. K. *Tsetse Fly Operations. Short Survey of the Operations by Districts for the Year ending December 1943. Rhodesia Agric. J.* 1944 v 41 No. 6 412-19. Summary taken from *Rev. Applied Entom.* Ser. B. 1946 Jan. v 34 Pt. 1 15.]

There was little improvement in the position as regards trypanosomiasis of cattle in the Chipinga area of the Maseru District, on the eastern border of

Southern Rhodesia, in 1943. The total number of tsetse-flies caught on the Rhodesian side of the border was 20 comprising 11 males and five females of *Glossina pallidipes* Aust., and three males and one female of *G. brevipalpis* Newst. while 15 males and 13 females of the former and one male and two females of the latter were taken in the clearing on the Portuguese side. Extensive additions were made to the main border clearing. Patrols carried out in Portuguese East Africa and on the border farms indicated that *G. morsitans*, Westw. has not spread much further up the Busi Valley, though individuals were caught about one mile from the border. A light infestation of this species was found in the lower Sabi Valley inside Southern Rhodesia during the year and trypanosomiasis caused heavy mortality among cattle in the neighbourhood. It is not anticipated that the Sabi and Lundi Rivers will act as effective barriers to the westward spread of the fly as they carry little water in the dry season. The Portuguese Government has declared a large area in Portuguese East Africa along the border east of the Melssetter district an open area for the destruction of all classes of game. This may have highly beneficial results in the control of *G. morsitans* if intensive shooting operations can be organised. The presence of tsetse on the border in the Vila Gouveia area of Portuguese East Africa opposite Inyanga has been notified.

Satisfactory progress was made in the northern areas infested by *G. morsitans* fly densities over the whole area covered by the operations showing a progressive reduction. No cases of animal trypanosomiasis were recorded from these areas. *G. pallidipes* was found to occur some distance south of its previously known limits in the Sebungwe district. The north-eastern boundary of the area remains heavily infested. Eight more cases of sleeping sickness were recorded from the Urungwe district, three foci of the disease being now recognised. The situation in individual districts is briefly reviewed and incidental aspects of tsetse control are discussed.

LAUNOY L. Albuminurie de la trypanosomose expérimentale à *T. annamense* du lapin: action des agents trypanocides. I. Action du moranyl employé seul. [The Action of Trypanocidal Agents on the Albuminuria of Experimental Infection with *Trypanosoma annamense* in the Rabbit. I. The Action of Moranyl alone.] Bull. Soc. Path. Exot. 1944, 37 Nos. 11/12, 347-58, 4 graphs.

Different opinions have been expressed on the importance of the albuminuria which often occurs during the treatment of human trypanosomiasis with Bayer 205, as the author could always cause albuminuria in rabbits by infecting them with his strain of *T. annamense*; he decided to make experiments to get an answer to two questions: (1) Can moranyl [Bayer 205] cause albuminuria in a rabbit with healthy kidneys? (2) what effect has treatment with moranyl on the albuminuria of trypanosomiasis?

He first injected various amounts of moranyl at various intervals into rabbits [4] and estimated the albumin, urea and chlorides in the urine. Slight albuminuria was produced but it soon disappeared. He then infected rabbits [3] with *T. annamense* and treated them with moranyl; this cured the infection and the albuminuria also disappeared. The figures of the excretion of urea and chlorides gave no indication of serious damage to the kidney, having been produced. Details of the experiments are given.

The author concluded that a single dose of 0.02 to 0.05 gm. (even 0.1 gm.) per kgm. does not cause albuminuria and that doses of 0.02 to 0.05 gm. per kgm. repeated less than four times at intervals of 1 to 5 days have little toxic effect on the kidney. Slight albuminuria, oliguria and hypochloruria are produced. With an interval of 14 days between injections, even doses of 0.1 gm.

per kgm. have little toxic action on the kidneys. Trypanosomiasis causes albuminuria 2 to 3 weeks after infection. It is cured by moranyl before the drug produces its slight irritant effect on the kidneys. These experiments offer no evidence that albuminuria due to trypanosomiasis is a contraindication to treatment with moranyl alone.

LAUNOY L. L'albuminurie de la trypanosomose expérimentale à *T. annu* *maruss* du lapin. action des agents trypanocides. II. Action de la synergie moranyl-anthiomaline. [The Action of Trypanocidal Agents on the Albuminuria of Experimental Infection with *T. annu* *maruss* in the Rabbit. II. The Action of Moranyl and Anthiomaline.] *Bull. Soc. Path. Exot.* 1945 v 38 Nos. 9/10 275-8.

The course of an infection of *Trypanosoma annu* *maruss* in a rabbit and the effects of treatment with moranyl and anthiomaline, administered simultaneously, are recorded in full detail. Treatment was delayed until the 47th day after inoculation, the animal being then very ill. The effects were similar to those produced in previous experiments with treatment by moranyl alone [above]. The two drugs were injected together, anthiomaline intramuscularly and moranyl subcutaneously, on the 47th, 51st and 57th days of infection. On the 60th day an injection of trypanamide was given. Albuminuria soon disappeared and the rabbit quickly recovered. The author concludes that synergic treatment with anthiomaline and moranyl in suitable dosage is not contraindicated by the presence of albuminuria.

RODHAIN J. & RESELER, R. Essai de différenciation sérologique entre trypanosomes et schizotrypanosomes. [An Attempt to differentiate serologically between Trypanosomes and Schizotrypanosomes.] *Ann. Soc. Belge de Méd. Trop.* 1945 June 30 v 25 Nos. 1/2 23-37.

The only species of trypanosomes which multiply within the cells of the vertebrate host are *T. cruzi* and *T. pipistrelli* (of the bat); they multiply by binary fission, not by schizogony. The authors made serological tests to see whether these species could be distinguished in this way from other species of trypanosomes. They used *T. brucei* maintained for several years in mice and rats, *T. cruzi* maintained in a species of bug (*Reduvius prolixus* (*fumatus*)) and in guinea-pigs, *T. pipistrelli* in culture and *T. vesperilionis* also in culture, and they had also a rabbit infected with *T. equiperdum*. To obtain specific antisera rabbits were infected with *T. brucei* and with *T. cruzi* and injections of large total amounts (nearly 100 cc.) of cultures of *T. vesperilionis* and of *T. pipistrelli* into rabbits were made during several weeks. The tests used were complement fixation, precipitin reaction and agglutination; the details are shown in tabular form.

All the precipitin tests were negative; the complement fixation tests indicated that there was an antigenic relationship between *T. cruzi* and *T. vesperilionis*, less between *T. cruzi* and *T. equiperdum* and still less between *T. cruzi* and *T. pipistrelli*. The agglutination tests indicated that *T. cruzi* and *T. pipistrelli* had a common agglutinin which was not present in *T. vesperilionis*.

The only final conclusion was that the two species of trypanosome (*Schizotrypanum*) which multiply within the cells of the vertebrate host cannot be distinguished from other trypanosomes by serological tests.

LEISHMANIASIS

ARMSTRONG T G Asymptomatic Kala-Azar in Soldiers from Over-Seas
Brit Med J 1945 Dec. 29 918

Two cases are described in which fever was slight and toxæmia absent with the result that kala azar remained for some time unsuspected. The first was in a soldier 20 years of age who served for a year in N Africa before transfer to Salerno and Naples. Eighteen months after leaving N Africa he was ordered by his sergeant to report sick. On being questioned he admitted a slow onset during five months of malaise, loss of weight and lassitude and he was easily fatigued. He was thin and anaemic with a low-grade pyrexia up to 99°F. The spleen was so soft that several weeks elapsed before the author finally decided that it was actually enlarged. In view of a leucopenia and granulopenia, a marrow puncture was performed, with the result that leishmania were discovered. Under stilbamidine treatment the patient made a slow and uneventful recovery.

The second patient returned to England in January 1944 after a year's service in N Africa, being invalided for diphtheritic polyneuritis. He recovered completely from this and finally came up for demobilization in September 1945 when he was found to have a greatly enlarged spleen. He made no spontaneous complaint, but on being questioned admitted some dyspnoea on exertion. Examination showed few if any signs apart from those attributable to the large spleen which extended well below the umbilicus. There was a low red cell count and a leucopenia. Marrow puncture showed leishmania which were also found by inguinal gland puncture.

The author points out that cases of kala azar are likely to be encountered occasionally in England and that unless the disease is borne in mind it may easily be overlooked. In both the cases described the patients when pressed admitted minor symptoms of several months duration, but these they had regarded as so slight as not to warrant attendance at sick parade.

SEN GUPTA, P C. Complement-Fixation Test with Witebsky, Klingenstein, Kuhn (WKK) or similar Antigens: a Modified Technique. *Indian Med Gaz* 1945 Aug v 80 No 8 396-8

In previous papers [this *Bulletin* 1944 v 41 17 1945 v 42 358] the author has given an account of his experiences with the complement fixation test for kala azar when the WKK antigen prepared from the acid fast bacilli of KEDROWSKY and of LLERAS was employed. His further experience has shown that a certain modification of the technique ensures more reliable results. This involves the titration of antigen and complement in a 1:25 dilution of serum instead of in saline and ensures that the titration is made under the conditions that exist in the test proper. It is confirmed that in the absence of severe leprosy and post kala azar dermal leishmaniasis a positive result is indicative of kala azar. A negative reaction is given by only 1 per cent. of all untreated cases in Calcutta and these appear to be very early cases. The fact that a small number of obvious cases of chronic pulmonary tuberculosis give a positive reaction cannot obscure the diagnosis.

Those who wish to carry out the test must consult the original article for full details of the technique.

The only species of trypanosomes which multiply within the cells of the vertebrate host are *T. cruzi* and *T. pipistrelli* (of the bat): they multiply by binary fission, not by schizogony. The authors made serological tests to see whether these species could be distinguished in this way from other species of trypanosomes: they used *T. brucei* maintained for several years in mice and rats; *T. cruzi* maintained in a species of bug (*Reduvius prolixus* (formatus)) and in guinea-pigs; *T. pipistrelli* in culture and *T. vespertilionis* also in culture, and they had also a rabbit infected with *T. equiperdum*. To obtain specific antisera rabbits were infected with *T. brucei* and with *T. cruzi* and injections of large total amounts (nearly 100 cc.) of cultures of *T. vespertilionis* and of *T. pipistrelli* into rabbits were made during several weeks. The tests used were complement fixation, precipitin reaction and agglutination: the details are shown in tabular form.

All the precipitin tests were negative: the complement fixation tests indicated that there was an antigenic relationship between *T. cruzi* and *T. vespertilionis*, less between *T. cruzi* and *T. equiperdum* and still less between *T. cruzi* and *T. pipistrelli*. The agglutination tests indicated that *T. cruzi* and *T. pipistrelli* had a common agglutinogen which was not present in *T. vespertilionis*.

The only final conclusion was that the two species of trypanosome (*Schizotrypanum*) which multiply within the cells of the vertebrate host cannot be distinguished from other trypanosomes by serological tests.

LEISHMANIASIS

ARMSTRONG T G Asymptomatic Kala-Azar in Soldiers from Overseas
Brit Med J 1945 Dec 29 918

Two cases are described in which fever was slight and toxæmia absent with the result that kala azar remained for some time unsuspected. The first was in a soldier 20 years of age who served for a year in N Africa before transfer to Salerno and Naples. Eighteen months after leaving N Africa he was ordered by his sergeant to report sick. On being questioned he admitted a slow onset during five months of malaise, loss of weight and lassitude and he was easily fatigued. He was thin and anaemic with a low-grade pyrexia up to 99°F. The spleen was so soft that several weeks elapsed before the author finally decided that it was actually enlarged. In view of a leucopenia and granulopenia a marrow puncture was performed with the result that leishmania were discovered. Under stilbamidine treatment the patient made a slow and uneventful recovery.

The second patient returned to England in January 1944 after a year's service in N Africa being invalided for diphtheritic polyn neuritis. He recovered completely from this and finally came up for demobilization in September 1945 when he was found to have a greatly enlarged spleen. He made no spontaneous complaint but on being questioned admitted some dyspnoea on exertion. Examination showed few if any signs apart from those attributable to the large spleen which extended well below the umbilicus. There was a low red cell count and a leucopenia. Marrow puncture showed leishmania which were also found by inguinal gland puncture. The author points out that cases of kala azar are likely to be encountered occasionally in England and that unless the disease is borne in mind it may easily be overlooked. In both the cases described the patients when pressed admitted minor symptoms of several months duration but these they had regarded as so slight as not to warrant attendance at sick parade.

SEN GUPTA P C Complement-Fixation Test with Witebaky, Klingenstein, Kuhn (WKK) or similar Antigens a Modified Technique. *Indian Med Gaz* 1945 Aug v 80 No 8 396-8

In previous papers [this *Bulletin* 1944 v 41 17 1945 v 42 358] the author has given an account of his experiences with the complement fixation test for kala azar when the WKK antigen prepared from the acid fast bacilli of KEDROWSKY and of LLERAS was employed. His further experience has shown that a certain modification of the technique ensures more reliable results. This involves the titration of antigen and complement in a 1:25 dilution of serum instead of in saline, and ensures that the titration is made under the conditions that exist in the test proper. It is confirmed that in the absence of severe leprosy and post kala azar dermal leishmaniasis a positive result is indicative of kala azar. A negative reaction is given by only 1 per cent of all untreated cases in Calcutta and these appear to be very early cases. The fact that a small number of obvious cases of chronic pulmonary tuberculosis give a positive reaction cannot obscure the diagnosis. Those who wish to carry out the test must consult the original article for full details of the technique.

FEVERS OF THE TYPHUS GROUP

LUSK, J. W. One Hundred and Fourteen Cases of Typhus Fever seen in an Indian Military Hospital in Calcutta. *Indian Med Gaz.* 1945 Sept. v 80 No 9 437-45 4 charts. [21 refs.]

This paper illustrates the difficulty so often experienced in India of determining to which vector-subgroup cases of typhus-group fevers belong. The author saw 114 cases during the months June to December 1943 of these 60 came from a village 80 miles from Calcutta and 54 from Calcutta and its environs.

The salient features have been extracted from the text and tables and are shown in tabular form [minor inconsistencies occur in the original tables] —

Serological type	Village cases	Calcutta cases	Total fatal
OXA	55 (4 fatal)	41 (7 fatal)	11
O19	3	9	0
O12	0	1 (fatal)	1
Clinical and P.M. evidence	2 (2 fatal)	3 (3 fatal)	5

Louse transmission seems to have been excluded, so that although the great majority of the cases can be assumed to have been mite-borne there may have been 12 flea-borne and possibly one or more tick borne cases.

No local lesion was seen in any case and only two patients showed appreciable lymphadenitis. A pronounced rash occurred in the O12 case in which also there was troublesome bleeding from the gums. In 14 other patients all of the OXA type a faint macular rash was detected.

[It would not be helpful to summarize the clinical and other features in detail because these would not be comparable with those seen in purely mite-borne outbreaks.]

SNYDER J C ZARAFONETIS C J D & LIU W T The Susceptibility of the Rodents, *Gerbillus gerbillus* and *Gerbillus pyramidum* to Experimental Typhus Infection. *Proc. Soc Exper Biol & Med* 1945 June v 50 No 2, 110-12.

Two rodents, *Gerbillus gerbillus* and *Gerbillus pyramidum* especially the were found highly susceptible to inoculation with the rickettsiae of louse-borne and murine typhus. Inoculation with large doses of either strain by nasal intraperitoneal or intravenous routes caused death in most of the animals within 3-8 days. The intravenous route was found most satisfactory.

Animals which had recovered from sub-lethal doses of either strain of rickettsia were immune to heavy doses of infection by both strains.

G. gerbillus after subcutaneous inoculation with two relatively small doses of louse-borne typhus vaccine became immune to a lethal dose of the same strain of rickettsiae.

After sub-lethal doses of either strain of infection, complement-fixation antibodies were found for the homologous strain there was a slight degree of cross fixation.

The Well-Felix reaction was negative in the few animals tested after infection. *G. gerbillus* was slightly less susceptible to fatal infection than the Eastern cotton rat *Sigmodon hispidus hispidus*. No gerbills of either species was found naturally infected. The animals used in the experiments were trapped in the desert near Cairo where they abound.

ZARAFONETIS C J D The Susceptibility of the Rodents, *Gerbillus pyramidum* and *Gerbillus gerbillus* to Experimental Tsutsugamushi Infection (Scrub Typhus) *Proc Soc Exper Biol & Med* 1945 June v 59 No 2, 113-16

Four strains of rickettsiae isolated from scrub-typhus patients in Imphal Calcutta and Ceylon were transmitted with equal success through series of passages maintained mostly by intraperitoneal inoculation in the two species of gerbilles used in the experiments described in the immediately preceding paper. When large doses of infected peritoneal washings were given by subcutaneous intraperitoneal, or intravenous injection death invariably resulted in 9-12 days and numerous rickettsiae were found in the abundant peritoneal and pleural exudate. The smears were stained with a 1 per cent solution of methylene blue this was found more satisfactory for *R. orientalis* than Macchiavello's stain which coloured the organisms blue instead of the fuchsin red tint taken on by other species of rickettsiae.

The gerbilles are regarded as suitable substitutes when white mice are not available.

DAVIS W A [U.S.A. Typhus Commission] Typhus at Belsen. 29 mimeographed pp 4 tables & 1 map [Field Headquarters APO 887 U.S. Army dated 26 July 1945]

This description of the work of the Typhus-Control Unit at Belsen Camp is necessarily a gruesome document. The author who belonged to the U.S.A. Typhus Commission was placed in sole charge of the Unit on April 21 1945. The horrible conditions prevailing in the Camp are now so widely known that no reference to them is needed.

The Unit began its work about five days after contact had been made with the Camp and completed its task on May 25. It dealt solely with preventive measures which consisted almost entirely in the systematic disinfection of the internees with DDT powder and the inoculation with typhus vaccine of the personnel engaged in the work. For most of the time the DDT powder available was of 5 per cent strength the 10 per cent strength urgently asked for by the author was delayed in arrival.

The degree of overcrowding that prevailed is shown by the fact that in many rooms at least 24 persons were confined in a space approximately 6 ft. wide 12 ft. deep and 8 ft. high. The occupants were not allowed to go out except for a few hours in the afternoon they lay two in each bunk and on the floor.

May 1946

Tropical Diseases Bulletin.

On the entry of British troops about 45 000 internees were alive in Camp 1 and about 10 000 corpses were still unburied. Among the living there were about 5 000 cases of famine oedema, 3 500 of typhus 20 000 of enteritis and 10 000 of tuberculosis. In Camp 2 there were 16 000 internees.

The first task was to bury the dead erect latrines, clear away excrement, establish a water supply and begin the evacuation of the "fit". A large 10-gun power duster was assembled by April 22 and all persons sent to 50 000 persons had been bathed and disinfested before admission.

The effect of disinfection was spectacular the last attack of typhus among the internees was on May 14 so that obviously the epidemic had been brought to an abrupt end. This result was strong evidence that transmission had been by living lice rather than by the dried faeces of the insects and it was brought about in spite of failure to achieve 100 per cent. destruction of the lice. Cases continued to occur among the attendants on the sick, but though the patients had been disinfested the possibility of transmission by live lice could not be excluded. Among 98 British medical students who worked at the camp there were six cases of the fever among British workers at Belsen was 8.5

The average duration of the attacks was severe. The German medical officer in charge of the nurses refused to allow them to be inoculated on the ground that this had already been done but afterwards it was admitted that they had not received any vaccine.

The only group of helpers who remained free from infection were the members of the American Field Service Unit the author seems to suggest that their special immunity was due to their having received the Cox type of vaccine whereas the others had received the Craigie type. [In the absence of information regarding the degree of exposure to risk, the time of inoculation, and possible earlier vaccination this suggestion should be received with reserve.]

About 10 persons were disinfested with each pound of powder
John W D Megees

SILVA, R. & KORCIOWSKA, Léonie Contaminations de laboratoire chez les individus vaccinés dans le typhus exanthématique. [Laboratory Infection with Exanthematic Typhus in Vaccinated Persons.] Bull. Soc. Path. Exot. 1945 v 38 Nov. 11/12 320-23.

A laboratory worker had received nine doses of vaccine at intervals of about seven days. The first seven doses were of murine and the last two of bivalent vaccine. Eight days after the end of the course of vaccination he was attacked by typhus fever of a very mild type. The complement-fixation titre with classical antigen rose to 1-640 and with murine antigen it rose to 1-160 so the diagnosis was classical typhus.

Another worker had received five doses of bivalent vaccine, and nearly five months later he had a very mild attack in which the complement-fixation titre rose to 1-640 with both classical and murine antigen. On the strength of this the diagnosis of "mixed infection" was made.

[The term mixed infection presumably means an infection due to *Rickettsia prowazekii* and *R. mooseri* if so, most observers would hesitate to base so complement fixation findings as satisfactory evidence on which to base so inherently improbable a diagnosis especially in the case of a person who had received bivalent vaccination.]
John W D Megees

Plotz H & WERTMAN K. Modification of Serological Response to Infection with Murine Typhus by Previous Immunization with Epidemic Typhus Vaccine. *Proc Soc Exper Biol & Med* 1945 June v 59 No 2 248-51

The responses to the complement fixation and rickettsia-agglutination tests are normally very consistent among persons attacked by epidemic (louse borne) and endemic (flea borne) typhus fevers. Much higher titres are observed in tests made with the homologous than in those made with the heterologous antigen. The authors found that among patients who had previously been protected by epidemic typhus vaccine anomalous responses were obtained, as can be seen from the table compiled from three tables illustrating the paper. The first two examples in the table show the kind of responses usually obtained in unvaccinated persons about the end of the third week of attacks of epidemic and murine typhus. The other entries relate to patients suffering from murine typhus who had been vaccinated during the previous two years with the epidemic typhus vaccine used in the U.S.A. Army. The interval since vaccination is shown in brackets.

	Disease	Day of disease	Weil-Felix titre		Complement fixation titre		Rickettsia agglutination titre	
			OXY19	OX2	Epid.	Murine	Epid.	Murine
Unvacc.	Epidemic T	19	2,560	80	640	0	5 120	1,280
Unvacc.	Murine T	20	160	0	0	160	640	10 240
Vacc. (2 y)	Murine T	21	2,560	0	640	320	80	1 280
Vacc. (3 m.)	Murine T	22	160	0	1 280	640	320	640
Vacc. (1 m.)	Murine T	21	320	0	160	160	5 120	10 240
Vacc. (3 m.)	Murine T	18	1 280	0	640	160	5 120	10 240
Vacc. (?)	Murine T	15	640	320	80	10	1 280	5 120
Vacc. (2 m.)	Murine T	24	80	40	320	320	1 280	5 120

The anomalous response persisted till late convalescence for example in two patients tested on the 159th and 70th days respectively in both of whom the epidemic complement fixation titre was 1-320 and the murine titre 1-160 though the murine rickettsia-agglutination titres were 1-2,560 and 1-1 280 respectively and the corresponding epidemic titres were 1-320 and 1-160.

No such anomalous reactions were observed in persons suffering from various other diseases due to virus bacterial or protozoal infections so the authors conclude that the unusual reactions are due to previous immunization with rickettsial products followed by infection with murine rickettsiae.

It was observed that previous immunization with epidemic typhus vaccine had little or no effect on the severity of the subsequent attacks of murine typhus.

RUMREICH A. S. & KOEPKE Jean A. Epidemiological Significance of Seasonal Variations in Rodent-Ectoparasite Distribution. *Pub Health Rep* Wash 1945 Nov 30 v 60 No 48 1421-8 2 figs [18 refs.]

The object of this investigation was to obtain epidemiological evidence of the relative importance of the various potential vectors of endemic typhus. Very large numbers of rats were trapped throughout the year and their ectoparasites were identified and counted. The localities investigated were Jacksonville Florida, Mobile Alabama and Honolulu. The numbers of rats examined in these places were 4 063, 6 123 and 6,382 respectively.

In Jacksonville the prevalence of *Xenopsylla cheopis* and of the mite *Laelaps kansasensis* corresponded to the incidence of endemic typhus when allowance was made for a time lag of one month in the occurrence of the disease. Both parasites were almost equally numerous.

A similar correspondence existed between *X. cheopis* and endemic typhus in Mobile but the correlation with *L. kansasensis* was practically nil. *X. cheopis* was more abundant than the mite in the ratio of 1.7 to 1.0.

The findings in Honolulu were quite different—the prevalence of *X. cheopis* was not correlated with the incidence of the disease and although some correlation occurred in the case of *L. kansasensis* it was not statistically significant. The mite was more abundant than the flea in the ratio of 3.5 to 1.0.

The rat mite *Liponyssus bacoti* which experimentally is a proved vector was found in insignificant numbers in Mobile and Honolulu—it was so erratic and contraseasonal in Jacksonville that it could not have been an important vector. None of the other ectoparasites of the rat could be suspected of being a vector on the evidence obtained.

The imperfections incidental to the survey are discussed, but after giving the fullest weight to these the authors are of opinion that *X. cheopis* may be accepted as at least an important vector in Jacksonville and as the principal vector in Mobile—but the available evidence does not support the assumption that this flea plays an equivalent rôle in Honolulu. The mite *L. kansasensis* is dismissed on the ground that it has not been shown to be infectible either in nature or experimentally.

[The findings on which the authors have based their conclusions cannot be abstracted, the whole paper deserves close study by all who contemplate making an investigation of the same kind—a vast amount of highly skilled work has been involved in its production, and few workers can hope to command either the opportunity or the special knowledge needed for carrying out so complete a survey.]

The authors have not referred to the question whether the lack of correlation between the prevalence of *X. cheopis* and typhus fever in Honolulu is actually opposed to the assumption that the flea is the principal or sole vector in the area. It may be impossible to give an answer to this question because, if a vector were present in numbers sufficient to maintain transmission the prevalence of the disease might well depend on other factors as well as on the density of population of the vector.]

TATTERHALL, R. N. & PARRY, T. E. An Outbreak of Typhus Fever (O.K.) in India. *Indian Med. Gaz.* 1945 Sept. v. 80 No. 9 433-7 2 figs. on 1 pl., 2 text figs. & 4 charts.

This report deals with 121 cases of "typhus fever (O.K.)" occurring in a British regiment during October and November 1943 in an area "adjacent to Burma."

The regiment went into camp in the affected area on October 11, 1943 and remained till November 2. The first case occurred 9 days after arrival, and the last 17 days after departure from the area.

Some of the chief clinical features were as follows (the figures in brackets show percentage incidence)—frontal headache with photophobia (100) sore throat (83) cough (9) a rash was seen in 79 cases it was macular in 39 and papular in 40 generalized adenitis (85) mental apathy (99) sometimes amounting to coma cyanosis and flushing (95) chest signs (88) conjunctival injection (69) deafness (33) and secondary fever (17).

The Weil-Felix (O.K.) titre usually reached 1-200 by the 13th day. The maximum readings were obtained between the 13th and 22nd days and after

this the titre tended to fall. The Dreyer technique and standard army suspensions were used. The average leucocyte count in the second week was 5 400 per cmm. The average differential count was polymorphonuclears 47 per cent lymphocytes 46 per cent and monocytes 6 per cent. Eosinophilia was common in the 4th and 5th weeks. There were 11 deaths.

A poor response to the exercise tolerance test persisted for three to four weeks [presumably after defervescence].

Post mortem examinations were made in all the fatal cases. The right side of the heart was dilated in ten, there was extreme pulmonary congestion in ten, pneumonia in six, enlarged mesenteric glands in all, congestion of the meninges and surface of the brain in all, and petechial haemorrhages in the stomach, ileum, caecum or colon in five.

John W D Megaw

GRIFITHS J T Jr A Scrub Typhus (*Tsutsugamushi*) Outbreak in Dutch New Guinea. *J Parasitology* 1945 Oct v 31 No 5 341-50 5 figs

In this outbreak there were 931 cases with 34 deaths among U.S.A. troops who landed on July 30 1944 on a coast in the Vogelkop Peninsula of Dutch New Guinea.

More than 500 of the cases were contracted in semi-cleared areas covered with knee-high grass growing on moist soil. There were also scattered cocoanut banana papaya and kapok trees remains of village sites small plantations and native gardens.

The incidence was low (28 cases) in two islands covered with cocoanut trees among which a dense undergrowth had sprung up so that only small amounts of grass and scrubby growth remained. The scantiness of the grass was suspected of being the cause of the smallness of the mite population.

Another area consisted of a strip of grass and ground-clinging vines along the beach backed by forest. From this environment there were 90 cases but the incidence was low compared with that in the first area. Most of the military base consisted of dense forest where no grass grew. In this area no cases occurred though scrub itch was common.

The incubation period was 7-17 days. The outbreak rapidly reached its height by August 15 about this time an average of 45 cases was being admitted daily but soon a rapid decline set in by the middle of September the daily admissions had fallen to three or four and at the end of the month an average of only one case daily was occurring.

The removal of grass and undergrowth from a site was found an effective method of control when the top soil had dried out the area was considered safe. There was no evidence that rat control was of any practical value. Impregnation of clothing with a soap emulsion containing dimethyl phthalate was strikingly successful.

Some of the clinical features observed in a sample group of 275 patients were as follows (the figures show percentage incidence): eschar with local lymphadenitis (92) photophobia (45) insomnia (75) generalized lymphadenopathy (95) and measly rash on body and limbs (28). The commoner sites of the eschar were the axillary region (24) scrotum (20) thighs (11) inguinal region (8) and penis (8). The temperature usually fell by lysis (70) when it fell by crisis (30). The attacks were much less severe on the whole and the convalescence was more rapid.

Of the 34 deaths in the whole outbreak (3.65 per cent.) 18 occurred on the 11th to 14th day 10 on the 15th to 18th day and 6 on the 20th to 26th day from the onset.

DESMOND M. D. Clinical Picture of Scrub Typhus in East African Troops on the Burma Front. *East African Med J* 1945 Nov. v 22 No 11 360-67

During the last quarters of 1944 615 cases were treated in a General Hospital for East African troops in Burma. The author describes some features of the disease as seen in 200 cases selected for their severity and interesting complications. The incubation period was two to three weeks.

Generalized lymphadenitis was usual. A primary sore was seen in 35 cases and a rash, usually inconspicuous and macular in 15. Nearly all the patients complained of pains in the bones and joints. Eight patients became insane two of them appeared unlikely to recover and one having cut his abdomen open with a razor blade ripped off the intestines from the mesentery.

Various types of neuritis occurred affecting the auditory nerve in eight cases, the facial in two, the laryngeal in two, the optic in one, nerves of the legs in six, and of the arms in one. Abscesses after injections were common, there was phlebitis of the femoral vein in two cases, and suppurative parotitis in one. Of the 615 patients 12 died, nine of these had been evacuated between the 6th and 11th days when transfers after the 4th day were forbidden the fatality rate became negligible.

The naked-eye post-mortem findings were uniform and rather disappointing. The lungs were congested, the heart was flabby but normal in size, the spleen was enlarged, soft and friable, the kidneys were congested, the mesenteric glands were enlarged, there was usually pinpoint haemorrhages in the stomach and intestines, and there was congestion of the superficial vessels of the brain. The microscopic findings were endothelial swelling and proliferation in the capillaries of the brain, but no perivascular aggregation of cells was seen. The cells of the renal tubules were swollen and necrosed, and there was endothelial proliferation in the lymph glands.

The Weil-Felix reaction (*Proteus OXK*) was of the usual type.
John H. D. Mogar

SOKOLOV M. & GARLAND L. H. Cardiovascular Disturbances in Tsingtau. *Disease. U.S. Nav. Med. Bull.* 1945 Dec. v 43 No 6 1054-68, 6 figs. [14 refs.]

The after effects of scrub typhus on the cardiovascular system were studied in 35 convalescent patients at an average interval of 4.7 months after the onset of the attacks. All the patients had been ambulatory for at least six to eight weeks, many of them for three months.

The exact significance of the findings cannot be estimated because there was no information to show what proportion of the total number of convalescents was represented by the patients. It was thought possible that the 35 men formed a relatively small percentage of the total. [Apparently they had been sent for special observation and treatment.]

The special symptoms were weakness, dyspnoea, palpitation of varying degree and precordial pains. Electrocardiograms showed no gross abnormalities in any case, but minor defects were found in seven cases. There was X-ray evidence of definite cardiac enlargement in four patients of whom one had appreciable enlargement of the left ventricle. In 14 of the patients roentgen-kymograms showed abnormal contractions affecting the left ventricle in all but one of them.

Decrease in the vital capacity was seldom pronounced, but 75 per cent. of the patients could not hold their breath for the normal time of 45 seconds, and in seven cases the maximum time was only 20 seconds.

Two-thirds of the men had tachycardia on standing and nearly half of them had abnormally high pulse rates after mild exercise tests. About 75 per cent had dyspnoea, palpitation, fatigue and dizziness after the standard exercise tolerance test.

All the evidence went to show that the defects were due to scrub typhus because a group of men who had been exposed to malaria, dysentery and other adverse conditions to the same degree were found free from these defects.

The pathogenesis of the condition is discussed. It is left an open question whether the chief factor was myocarditis, peripheral vaso-motor instability or perhaps lesions of the cerebral vaso-motor centres.

Progressive improvement resulted from treatment. The conclusion reached is that convalescence in many cases of tsutsugamushi disease is protracted and that disabling circulatory disturbances may persist in some cases up to at least six months from the onset.

MURRAY E S ZARAFONETIS C J D & SNYDER, J C. Further Report on Effect of Para-Aminobenzoic Acid in Experimental Tsutsugamushi Disease (Scrub Typhus). *Proc Soc Exper Biol & Med* 1945 Oct., v 60 No 1 80-84

Experiments are described which demonstrate that para aminobenzoic acid can greatly reduce the fatality rate among gerbilles inoculated with lethal doses of *Rickettsia orientalis*. The sodium salt (NaPAB) was used and was given by a combined method—orally with food starting a few hours after intraperitoneal inoculation with the rickettsiae and also subcutaneously starting on the 4th or 5th day after inoculation.

The results obtained in the whole series of experiments were that among 130 control animals only two (1.5 per cent) survived whereas among 128 treated animals 105 (82 per cent) survived. Most of the animals received 10-1000 certainly lethal doses of rickettsiae and very few of the animals that died in spite of treatment showed the typical lesions of the disease at autopsy. The strains of rickettsiae used in the trials originated from Calcutta, Ceylon, Imphal and New Guinea.

Details of the preparation of NaPAB and of the method of administration are given in the paper.

John W D Megaw

SNYDER, J C. & ZARAFONETIS C J D. Effects of Para-aminobenzoic Acid in Experimental Tsutsugamushi Disease (Scrub Typhus). *Proc Soc Exper Biol & Med* 1945 Oct. v 60 No 1 115-17

This paper contains a description of experiments carried out before those referred to in the preceding abstract. PABA was given mixed with the food to gerbilles after intraperitoneal injections of 100 to 1000 lethal doses of *Rickettsia orientalis* but the only result was a slight prolongation of the survival time.

The early experiments on the combined oral and parenteral treatment with sodium salt of PABA (NaPAB) are also described. In these the survival rates after 10-100 lethal doses of the Ceylon strain were 87½ and 62½ per cent respectively.

ROSE H M DUANE R B & FISCHER E E. The Treatment of Spotted Fever with Para-Aminobenzoic Acid. *J Amer Med Ass* 1945 Dec. 22 v 129 No 17 1160-61 1 chart.

Para aminobenzoic acid (paba) has already been found effective in the treatment of louse-borne typhus in man by LEOMANS and his colleagues [see this

tested in the following way — A group of 50 Swiss mice received three doses each of 0.25 ml. intraperitoneally at weekly intervals. Ten days after the last dose they and 50 unvaccinated mice, were challenged, in groups of eight, with intraperitoneal injections of spleen substance from infected mice. The dose of infected material was graduated by dilution in ten-fold steps from 10^{-1} to 10^{-8} . The numbers of mice dying within 25 days after being challenged are shown. The infecting doses are arranged in descending series, beginning from the left —

Vaccinated	5	3	2	1	3	0
Controls	8	8	7	8	6	4

After vaccination by the subcutaneous route with similar doses, the comparable figures for four groups of 10 mice each were as follows —

Vaccinated	7	6	2	5
Controls	10	9	8	4

The significance of the results is discussed. It is admitted that the vaccine seems to give poor protection compared with the results obtained in mice protected against epidemic typhus by epidemic type vaccine but in view of the intense susceptibility of the mouse to scrub typhus it was thought that this impression might be misleading as epidemic and scrub typhus in man are so similar in their clinical features, there seems some reason to hope that the vaccine against the latter may prove as effective as the epidemic type vaccine.

The doses which have been suggested for trial in human beings are three of 1.0 ml. each given at weekly intervals and a "booster" dose of 1.0 ml. every three months.

The authors finally point out that without a field trial, it is impossible to decide whether this vaccine will be of any value in man.

BUCKLAND F. E., DUDGEON A., EDWARD D. G. H., HENDERSON BEGG A., MACCALUM F. O., NIVEN J. S. F., ROWLANDS, L. W. & VAN DEN ENDE, M. with H. E. BARGMAN, E. E. CURTIS & M. A. SHEPHERD. Scrub-Typhus Vaccine. Large-Scale Production. *Lancet* 1945 Dec. 8 734-7 8 figs.

The authors tell the remarkable story of "Special Operational Store-Tyburn," which was organized for the large-scale preparation of scrub-typhus vaccine on the lines described in the immediately preceding paper with the object of carrying out field trials in the Far-Eastern war zone.

A large laboratory was designed and constructed at Frant in Sussex. Housing for the breeding colonies of cotton rats was ready within 31 days and the complete laboratory was opened on May 31 1945 within 109 days of the decision to start the operation. This feat was made possible by the military priority accorded to the scheme.

All the rooms in which there was risk of infection were ventilated on the plenum system and were fitted with apparatus for the aerosol-spray treatment of the air with lactic acid. Air from the special inoculating and grinding cabinets was extracted and passed through an electric furnace on the roof to prevent the discharge of infected particles into the open air. Details are given of the elaborate precautions against infection of the workers and among 60 persons employed only three were attacked by the disease. One person was suspected of having inhaled infected droplets while transferring material with a Pasteur pipette another had a skin trauma caused by a broken pipette containing infected material and the third had been washing unsterilized infected Petri dishes. All three made uneventful recoveries. They and the rest of the staff had been vaccinated.

The scheme was planned on the basis of importation from the U.S.A. of 5 000 cotton rats monthly this with local breeding was expected to provide 12 000 rats monthly. These rates were not attained altogether 19 223 rats were imported and 10 686 were bred up to the time of writing 16 882 had been used but about 20 per cent were discarded because of death before the fourth day or insufficient rickettsial yield. During the five and a half months ending September 30 201.9 litres of vaccine were prepared.

When the war against Japan came to an end the operation ceased to be urgent but it was continued till the available rats were used and by October 31 when 300 litres of vaccine had been prepared it came to an end.

The preparation of the vaccine was on the lines described in the preceding paper but a few modifications were introduced. The mice used for preparing infecting suspensions were given sulphathiazole in a concentration of 1.0 per cent in a cubed diet instead of by intraperitoneal injection. Smears were stained by alkaline polychromed methylene blue after heat fixation and treatment with $N/1$ HCl.

Altogether 15 100 mice were used to prepare the seed suspensions but of these 9 163 died or were discarded because of gross contamination. Each batch of vaccine was tested by rickettsial counts and complement fixation tests it appeared that the antigenic content was correlated with the rickettsial count though difficulties were encountered with the staining technique and probably the true counts were much higher than those actually observed. Several interesting pieces of research were carried out including further attempts with unsatisfactory results to cultivate the organisms by the yolk-sac method. Filtration experiments suggested that the size of *Rickettsia tsutsugamushi* corresponded closely with that of *R. prowazekii*. Attempts at serial passage through the lungs of sheep and goats failed.

[This brief summary is inadequate to convey a complete impression of a unique operation carried out at high pressure because of urgent military necessity. The paper itself is highly condensed and deserves to be read in its original form.]

YELLOW FEVER.

LAIRET F. Jr. La situación de la fiebre amarilla en Venezuela. [Yellow Fever in Venezuela.] *Bol. Oficina Sanitaria Panamericana* 1945 Sept. v. 24 No. 9 778-83 3 maps English summary

During 1929 an outbreak of jungle fever occurred in the Cuyuní Valley a sparsely settled wild region in Venezuela. This proved to be autochthonous as the settlements where the fever occurred are located at considerable distances from places where long before cases had been reported. Since the creation of the National Service for the Prevention of Yellow Fever in Venezuela in 1937 the yellow fever problem has been studied with great care continuously. There are 78 viscerotomy posts in operation where positive protection tests have been made. This organization has made it possible to locate another yellow fever area, as shown in one of the attached maps. During the 1929 outbreak in Cuyuní 11 cases occurred among laborers working in sawmills and other cases were reported in workers clearing timber areas and jungles where the *Haemagogus* vector prevails. An *Aedes belzebuth* or long-sleeve monkey caught in the San Camilo Forest showed a positive reaction to the disease. In brief there are in Venezuela two endemic jungle yellow fever areas both located in the basins of Maracaibo Lake and the

May 1946

tested in the following way — A group of 60 Swiss mice received three doses each of 0.25 ml. intraperitoneally at weekly intervals. Ten days after the last dose they and 50 unvaccinated mice were challenged, in groups of eight, with intraperitoneal injections of spleen substance from infected mice. The dose of infected material was graduated by dilution in ten-fold steps from 10^{-4} to 10^{-8} . The numbers of mice dying within 25 days after being challenged are shown. The infecting doses are arranged in descending series beginning from the left —

Vaccinated	5	3	2	1	3	0
Controls	8	8	7	8	6	4

After vaccination by the subcutaneous route with similar doses, the comparable figures for four groups of 10 mice each were as follows —

YELLOW FEVER.

LAIRET F Jr La situación de la fiebre amarilla en Venezuela. [Yellow Fever in Venezuela.] *Bol Oficina Sanitaria Panamericana* 1945 Sept 24 No 9 778-83 3 maps English summary

During 1929 an outbreak of jungle fever occurred in the Cuyuni Valley a sparsely settled wild region in Venezuela. This proved to be autochthonous as the settlements where the fever occurred are located at considerable distances from places where long before cases had been reported. Since the creation of the National Service for the Prevention of Yellow Fever in Venezuela in 1937 the yellow fever problem has been studied with great care continuously. There are 76 viscerotomy posts in operation where positive protection tests have been made. This organization has made it possible to locate another yellow fever area as shown in one of the attached maps. During the 1929 outbreak in Cuyuni 11 cases occurred among laborers working in sawmills and other cases were reported in workers clearing timber areas and jungles where the *Haemagogus* vector prevails. An *Ateles belzebuth* or long-sleeve monkey caught in the San Camilo Forest showed a positive reaction to the disease. In brief there are in Venezuela two endemic jungle yellow fever areas both located in the basins of Maracaibo Lake and the

Orinoco River. The first where the 1944-1945 outbreak centred, lies in the so-called Venezuelan Guayana, bounded by the Caroní river and the borders of the State of Bolívar with Brazil and British Guayana. The second is in the States of Táchira and Barinas its principal focus being in the so-called San Camilo Forest on the transitional area between the Andes Mountains and the Apure and Barinas plains. There may perhaps be another yellow fever focus at the northern watershed of the Andes towards Maracaibo Lake although up to the present time only one case has been reported.

KAPLAN M. & GLUCK, A. C. Méningo-encéphalite après vaccination anti-amarile. [Meningo-encephalitis after Vaccination against Yellow Fever] *Bull et Mem Soc Méd Hôpitaux de Paris*. 1945 Nos. 26/31 374-8.

The record of the clinical symptoms of a 4½-year-old child who became ill 5 days after being vaccinated, by the scarification method, with a neurotropic strain of yellow fever virus supplied by the Pasteur Institute at Dakar. This child developed typical meningeal symptoms about the 11th day after vaccination, with high fever headache somnolence, a convulsive crisis and a state bordering on coma. Lumbar puncture produced a clear aseptic fluid and showed a mononuclear hypercytosis. After two or three days there was sudden improvement and the patient made a complete recovery.

Attempts to isolate yellow fever virus from the cerebrospinal fluid by intracerebral inoculation of mice gave inconclusive results, but protection tests with the same fluid were positive. The authors are of the opinion that in order to avoid such accidents it is preferable to use inactive tissue culture virus for vaccination.

DENGUE AND SANDFLY FEVER

FLORIO L., STEWART Mabel O. & MUGRAGE, E. R. The Etiology of Colorado Tick Fever. *J Exper Med* 1946 Jan. 1 v. 83 No 1 1-10 6 figs.

The authors, continuing their work on Colorado tick fever [this Bulletin 1945 v. 42, 118] now report experiments on the filterability of the causal agent. Two strains were maintained by passage through hamsters, and serum from infected animals was used as the source of virus in filtration experiments. Hamsters were injected intraperitoneally with test filtrates, and lowering of the white blood count was taken as the criterion of successful infection. Both strains of virus were found to pass through 200 and 181µm collodion membranes. In seven experiments with filtrates of 24µm membranes two groups of hamsters showed clear-cut evidence of infection and the presence of the virus was demonstrated by passage in three other groups. A human volunteer developed Colorado tick fever following subcutaneous injection of infected hamster serum filtered through a 181µm membrane. Similar experiments with the filtrate of a 24µm membrane proved negative.

The authors conclude that the infectious agent of Colorado tick fever passes through 24µm membranes and should be classified as a virus.

PLAGUE

GIRARD G. Hémoculture et bactériémie dans l'infection pesteuse [Culture and Bacteraemia in Plague.] *Bull Soc Path Exot* 1944, v 37 Nos 11/12 328-31

An original question whether a flea can become infected when fed on a case in which blood culture has proved negative resolves itself for the author into two further questions —(1) How many organisms in a blood culture are necessary to initiate a plague culture? and (2) Are there any bactericidal or inhibitory substances carried over with the blood in a blood culture which would be sufficient to render non-viable a proportion of the organisms present? The media used for which the author expresses decided preference were one in which the peptone was Chapoteaut's peptic peptone and the other called Uclaf in which the peptone is a tryptic digest of foetal tissue to which gluten is added. In his experiments using dilutions of a suspension containing about 20 million bacteria per cc the author arrives at the conclusion that growth of the plague bacillus can be initiated in a suitable medium when the inoculum contains no more than a single living organism. This conclusion seems to provide the answer to the first of the two questions posed. The second question is dealt with firstly by showing that the addition of any blood to any nutrient medium will act favourably in the initiation of growth of the plague bacillus and secondly by showing that the addition of any blood of any animal whether a normal animal an animal which has proved resistant to large testing doses of plague or an animal which has been used to furnish plague serum (antitoxic not bactericidal) is immaterial so far as relates to any but a favourable effect on the growth of the plague bacillus. And thus the final conclusion may be reached that if a blood culture proves negative it is because that blood contains no viable organisms and that therefore no flea could become infected by ingestion of that blood. The blood of a plague case too contains no bactericidal or inhibitory substances which could complicate growth conditions.

W F Harvey

CHOLERA.

SOMAN D W & NAIR S K. Sub-Types of Cholera *Vibrio Isolated from Cholera Patients in Bombay Indian Med Gaz* 1945 Oct. v 80 No 10 512-14

A survey of the conditions in town or district during the prevalence of disease has great importance for epidemiology by presenting data for future comparisons and predictions. Such data in India are few and non-existent in Bombay. The authors have seized the opportunity of epidemic cholera during 1943 and 1945 in Bombay City to obtain and publish these data. They refer to the serological sub-types Inaba and Ogawa cholera vibrios of sub-group I. As the authors mention (and this is one aspect of the value of this Bombay survey)— Investigations carried out over a period of years in the Madras Presidency have shown extensions and recessions of the area in which the respective sub-types may be the form associated with outbreaks. Their findings given as a summary were The prevalent and predominant sub-types of cholera vibrios have been determined. One hundred and sixty four strains isolated have been tested against cholera O serum group I and Inaba and Ogawa specific sub-type sera. One hundred and sixty-one strains belonged to the Ogawa subtype the remaining three strains were found to be Inaba sub-type. No intermediate type was recorded.

W F Harvey

UNITED STATES NAV MED BULL. 1945 Dec. v 45 No 6 1049-53 Report on Cholera Studies in Calcutta, Value of Chemotherapy in the Treatment of Cholera and use of Blood Plasma in Cholera Collapse. Epidemiology Unit No. 50. [AMBRERSON J M.]

The object of this report is to show the value of chemotherapy in general it is not an analysis of the relative value of specific medicaments. A comparative series of trials was set up which contrasted no treatment other than the usual supportive treatment with chemotherapy which, of course, involved throughout also the usual supportive treatment. Very special consideration is paid to the use of blood plasma as supportive treatment along with chemotherapy. There was a total of 372 cases of clinical cholera available for analysis.

The groups in this report are set out as (A) 3 gm sulphaguanidine every 4 hours for 3 days and twice daily for the next 3 days to a total of 72 gm. (B) Supportive treatment only represented by intravenous hypertonic and normal saline solution together with oral stimulants to offset dehydration emaciation and circulatory failure. This group of patients the control group received inert substance (3 gm. calcium carbonate every 4 hours for 3 days) (C) One gm sulphadiazine every 4 hours for the first day, and 2 gm. every 4 hours for the following 2 days to a total of 30 gm. (D) Penicillin intramuscularly in normal salt solution the initial dose being 100 000 units with 25 000 units every 4 hours thereafter to a total of 200 000 units. (E) Received the combined treatments of C and D. Positive value is accorded to chemotherapy and in the matter of data particular stress is laid on the combination of supportive blood plasma with any or all of the chemotherapeutic groups. These data are set out in tabular form —

	Plasma plus chemotherapy	Chemotherapy alone	Control
Lived	33	274	37
Died	0	3	23
Death Rate	0*	1 1/2%	38 3%

There can be little doubt of the value of chemotherapy in cholera.

W F Harvey

BACILLARY DYSENTERY

SMITH L A. Shiga Dysentery *J Amer Med Ass* 1946 Jan. 5 v 130 No 1 18-22.

By "Shiga dysentery" the author means that due to any organism of the *Shigella* group in short bacillary dysentery. Mild attacks of diarrhoea or of dysentery [referred to by British troops as the squitters or Guppy tummy] are known to American troops as the G La. The early diagnosis of bacillary dysentery on clinical grounds, by microscopical examination of the stools, or by culture of the stools, may be misleading and is often impossible. Proctoscopy in the knee-elbow position is quite easy in a patient with diarrhoea, if performed after a natural motion and without enema clearance. This technique affords the earliest possible positive diagnosis of bacillary dysentery and on repetition shows the progress of the disease. The findings indicate three phases of development of the bowel lesions in bacillary dysentery viz —

(1) The *Early Phase* is to be seen within a few hours of the onset of symptoms the essential features are oedema and generalized hyperaemia of varying intensity of the mucosa. There may be miliary mucosal abscesses of pin point to pin head size initially these are creamy in colour and are due to localized accumulation of leucocytes later they are topped by shallow ulceration. In severe cases there may be superficial necrosis of the mucosa with the formation of a pseudo-membrane this on being stripped off leaves a red or purple raw surface which bleeds easily.

Efficient early treatment of bacillary dysentery in this stage causes rapid regression of the bowel lesions.

(2) The *Middle Phase* is characterized by granulations indicative of healing and by ulceration. The granulations vary in number and size are dusky red or purple in colour and are irregular in shape there may be central ulcers in them. These ulcers are from 0.5 mm. to over 1 cm. in diameter and are round oval or serpiginous their bases are grey and dirty. The proximal surfaces of the valves of Houston are a usual site for these lesions and a patient with much tenesmus will have many of them in the lower 6 cm. of the bowel. As healing progresses granulation fills in the ulcers the colour of the new tissue lightens and eventually the normal vascular pattern of the mucosa is restored perhaps many days after the patient is symptom free.

Efficient treatment of the dysentery at this stage is much more slowly effective in causing regression of the bowel lesions.

(3) The *Late Phase* is seen in severe untreated cases of bacillary dysentery where indolent ulceration persists for long and heals slowly often with extensive superficial scarring.

After discussing the differential diagnosis of bacillary dysentery and reaffirming that in 90 per cent. of cases early proctoscopy yields the diagnosis the author reviews the response to treatment of his cases symptomatically, objectively and in relation to the reversal of the cultural findings in the stools. Previously clinical response and the time taken to obtain it have been the criteria of success of treatment but these are misleading unless proctoscopic examinations are made. Four groups of cases were treated respectively—(1) without chemotherapy (2) with sulphaguanidine—4 gm. three-hourly for four doses and then 2 gm. four-hourly—a total of 46 gm. in 72 hours (3) with sulphadiazine (given with equal weights of sodium bicarbonate) 4 gm. initially then 2 gm. four-hourly for four doses then 1 gm. four hourly for four doses and then 1 gm. six-hourly for seven doses—a total of 23 gm. in 72 hours and (4) by combined sulphaguanidine and sulphadiazine therapy (sulphadiazine as outlined for three days on the third day sulphaguanidine as outlined this being continued until the fifth day).

The author concludes that the best period for effective treatment is in the first twenty four hours of the disease. Sulphadiazine at this time causes prompt cessation of the symptoms and signs but the mucosal lesions may not disappear until some time after this especially if treatment has been delayed. Sulphadiazine appeared to be more rapid in its action than sulphaguanidine and caused the stools to become negative on culture within 24 to 36 hours.

REDDY D G & RANGAM, C. M. Jaundice in Amoebic Liver Abscess. A Report of Two Cases. *Indian Med Gaz.* 1945 Oct. v 80 No 10 501-2, 4 figs. on 1 pl.

Two cases of amoebic abscess of the liver diagnosed at post mortem examination are described in one case a single abscess had ruptured into the peritoneal cavity while in the other case there were three abscesses in the right lobe of the liver but none had ruptured, though a diffuse peritonitis was present. Amoebae were found in the walls of the abscesses in both cases. Both patients were jaundiced in one case the abscess pressed on the right hepatic duct while in the other case the common bile duct was blocked. *J F Corson*

GILJE, L. E. & LAMPSON, R. S. Acute Appendicitis in Amoebic Dysentery Report of a Case. *U.S. Nav Med. Bull* 1948, Jan. v 46 No. 1 109-11

KMOLL, Elta W & HOWELL Katharine M. Studies on *Dientamoeba fragilis* its Incidence and possible Pathogenicity *Amer J Clin. Path.* 1945 May v 15 No 5 178-83. [19 refs.]

In discussing *Dientamoeba fragilis* the authors note that the various surveys in which it has been identified indicate that its distribution is widespread throughout the world. If laboratory workers were experienced in the identification of this parasite they would find that its incidence in any population is probably as high as or even higher than that of *E. histolytica*. As regards its possible pathogenicity a series of cases is described in children and adults in which it appeared to be the only organism present, apart from non-pathogenic bacteria. The symptoms in these cases were abdominal discomfort and pain bouts of diarrhoea, nausea and vomiting and some fever. During the attacks *D. fragilis* in very large numbers appeared in the stools. In some of the cases symptoms had persisted for two or more years. In all these cases the symptoms ceased under carbazone therapy while *D. fragilis* disappeared from the stools. As a result of their studies the authors conclude that *D. fragilis* can be pathogenic to man. Attempts to discover the organism in dogs cats and rats met with no success while repeated administration of rich cultures to kittens *per os* and *per rectum* failed to bring about an infection. *C M Wenyon*

DÍAZ ATILES A. A Study of *Balantidialis coli*. Report of Two Cases in Children successfully treated with Stovarsol. *Puerto Rico J Pub Health & Trop Med.* 1943 Mar v 18 No 3 287-99 [Refs. in footnotes.] [Spanish version 300-313.]

The author in reviewing recent literature gives an account of two cases of *Balantidium coli* infection in boys nine years of age both of whom had been in intimate contact with pigs. The persistence of the infection for six weeks was established by repeated stool examinations before treatment with stovarsol was instituted. In one case response to treatment was immediate the stools being negative after 48 hours but treatment was continued for a week. In the other case there was no response for three weeks. With increased dosage (750 mgm. daily) the stools became consistently negative. In both cases, a year after cessation of treatment the stools were still negative. Two other children are referred to they were associates of the others but treatment was not carried out as the infection from which they both suffered, was only of a transient nature. *C M Wenyon*

HUMPHREY A. A. *Isospora hominis* Infection in Man. *J Amer Med Ass* 1946 Jan 19 v 130 No 3 143-5 1 fig

Three cases of *Isospora hominis* infection are described in men who had served in Okinawa and were evacuated to Guam for hospital treatment in July 1945. All three suffered from abdominal discomfort or diarrhoea. The longest period during which oocysts were observed in the stools was during 15 days hospitalization. In all three cases there was some degree of eosinophilia.

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

GREAVES F C, GEZON H M & ALSTON W F. Studies on Louse Borne Relapsing Fever in Tunisia. *U.S. New Med Bull* 1945 Dec. v 45 No 6 1029-48 9 figs [49 refs]

A general account with special reference to the treatment and control of louse-borne relapsing fever due to *Spirochaeta berbera* in Tunisia.

Since the outbreak of 164 cases in Tunis during 1912 there were only sporadic cases until July 1943 when a major epidemic began which was still in progress during 1945. In 1943 only 6 cases were recorded but in 1944 the monthly cases rose from 8 in January to 4 451 in December and continued to rise in 1945 to 6 536 in March. The total for 1944 was 18 534 and for the first 4 months of 1945 reached 23,221 cases. These statistics are considered by the public health authorities to involve only one-fifth of the actual numbers for the majority of the Arab population seem to prefer not to attend for medical treatment.

The mortality rate showed marked differences. In one small village 80 untreated cases had a mortality rate of 1.25 per cent whilst in another very similar village 71 untreated cases showed a rate of 46.5 per cent. among 3 806 cases treated in the Ernest Conseil Hospital in Tunis the rate was 5.46 per cent. There is no satisfactory explanation for these differences and it is possible that other diseases such as typhus, typhoid, or plague may have complicated the relapsing fever.

The clinical symptoms were typical but 10 per cent. of 112 untreated cases had no relapses. 62.5 per cent. showed only one relapse and 22.3 per cent. two relapses whilst occasional cases showed three, four or five relapses. Laboratory studies were made on 40 patients. The most constant finding was a complete absence of eosinophils in all patients even after the clinical termination of illness.

Penicillin was used for the treatment of 27 patients the total dose being 480 000 units for adults and 360 000 for children. In most cases the spirochaetes disappeared within 24 hours and none was ever found after 48 hours. All these patients showed a rapid clinical recovery and none had a relapse. The results with neosarsphenamine were also equally satisfactory and since this is cheaper and easier to administer it is the drug of choice except when relapsing fever is accompanied by jaundice.

Three guinea-pigs and 27 mice were inoculated with infective material but only in the case of one guinea-pig and 21 mice receiving large doses of heavily infected blood were spirochaetes recovered and then only in the first 24 hours. It is evident that these animals are unsuitable for the isolation of this spirochaete directly from human blood.

Experiments were made on the control of the epidemic in an isolated Arab village by the use of 10 per cent DDT applied by dusting each member of the

household and the bedding and extra clothing. The disease completely disappeared within a fortnight after this treatment and neither lice nor nits were found on 75 people examined in the village 10 days later. Another experiment was made in Ferryville. In the treated area 76.7 per cent. of 851 persons were dusted with DDT. In the adjoining control area there were 1,438 persons. The results are shown in the following table—

Incidence of relapsing fever in the Bellevue quarter of Ferryville May 1945.

		Total	No. deloused	Percent deloused	No. nits	No. sick	Percent sick	No. with Positive Blood Smears
May 5-12	DDT	851	653	76.7	147	46	5.41	14
	Control	1,438	none	0.0	129	47	3.27	12
May 17-19	DDT					2	0.23	1
	Control					41	2.85	12
May 28-28	DDT					4	0.48	1
	Control					24	1.67	8

It would seem, therefore, that one application of 10 per cent. DDT powder if thoroughly applied to a population is almost completely effective in stopping a louse-borne epidemic of relapsing fever.

LOFGREN, Ruth & SOULE, M. H. The Structure of *Spirochaeta mors* as revealed by the Electron Microscope. *J. Bacteriology* 1945 Dec. v. 50 No. 6 679-80 8 figs.

RICHARDSON, A. P., WALKER, H. A., LOBB, Prudence & MILLER, I. The Experimental Basis for the Quantitative Chemotherapy of *B. mors* in Mice with a Comparison of Action of Penicillin and Dichlorophenarsine Hydrochloride. *J. Pharm. & Exper. Therap.* 1945 Sept., v. 85 No. 1 23-35 2 figs. [10 refs.]

The authors describe detailed experimental procedures for quantitative chemotherapeutic experiments with mice infected with *Spirochaeta mors*. They first show that the number of spirochaetes injected has a considerable effect on the course of untreated infections. Also that the degree of anaemia which develops is roughly proportional to the number of organisms in the peripheral blood.

Five samples of penicillin were tested for their action on the spirochaetes, viz. crystalline sodium penicillin G, commercial sodium penicillin Squibb, pilot plant lot No. 860 containing almost no penicillin G, commercial calcium penicillin Squibb, probably a mixture of G and other penicillins, and methyl ester of penicillin G. The activity of these five compounds was compared with dichlorophenarsine hydrochloride in three types of experiments, viz., frequent subcutaneous injections, single daily injections or given by mouth. On the basis of Oxford units, no significant differences were found between the first four samples of penicillin irrespective of the method of administration. The methyl ester of penicillin G was found to be equal to free penicillin G when injected, but had less than one-twentieth of that activity when given orally.

When administered by frequent subcutaneous injections dichlorphenarsine hydrochloride is weight for weight equal to crystalline sodium penicillin G in its activity against *Spirochaeta novyi*

NAJERA ANGULO L. Receptividad de los murciélagos cavernícolas españoles (*Myotis myotis*, *Rhinolophus euryale* y *Rh. hipposideros minimus*) al virus de la fiebre recurrente mediterránea [The Susceptibility of Spanish Cave-dwelling Bats to the Spirochaete of Mediterranean Relapsing Fever] Reprinted from *Boletín de la Real Soc Española Hist Nat Madrid* 1945 v 43 217-28 1 map

The relationship between *Spirochaeta hispanica* and the spirochaetes causing relapsing fever in Portugal and in Greece (*Sp. hispanica* var. *peloponnesica* of Caminopetros) is of considerable interest. The author calls the fever caused by these organisms Mediterranean relapsing fever. As biological reactions are important aids in the identification of spirochaetes of apparently identical morphology, he made experiments in 1939 to test the susceptibility of some cave-dwelling bats to infection with *Sp. hispanica*.

These bats were difficult to keep alive and it was found best to keep them at a temperature of 18°C and in an atmosphere of a humidity approaching saturation. To get a short incubation period they were inoculated intraperitoneally with blood of guinea-pigs heavily infected with *Sp. hispanica* and those which survived for 4 days or more were examined post mortem.

The results are shown in notes and tables. Four species were found susceptible namely *Myotis myotis*, *Rhinolophus euryale* and *Rhinolophus hipposideros minimus*. One of these bats *Myotis* is a host of *Schizotrypanum vespertilionis*.

TAFT W C & PIKE J B Relapsing Fever. Report of a Sporadic Outbreak including Treatment with Penicillin. *J Amer Med Ass* 1945 Dec. 8 v 129 No 15 1002-5

A study of eleven cases of relapsing fever observed and treated at an army hospital in Texas during August and September 1944 and April and May 1945. All the patients shortly before admission had camped in a bivouac area where many *Ornithodoros turicata* were present. Later it was shown that spirochaetæ infection was present in the ticks.

The clinical diagnosis of the disease in the initial stages was found to be difficult. It was established by dark field examination or stained smear of the peripheral blood. Spirochaetes were found in the blood only during the febrile period when the temperature was above 102°F. Five of the patients developed a skin eruption having the appearance of erythema multiforme which persisted for 24 to 48 hours. A biopsy was made of one of these skin lesions and spirochaetes were found in the superficial layers of the dermis even during the afebrile period. [This interesting observation seems to be the first record of relapsing fever spirochaetes being found in this site.]

Significant neurological manifestations developed in five of the patients even suggesting a diagnosis of meningitis. Spirochaetes were never found in the spinal fluid however either by direct examination or mouse inoculation. Treatment with oxophenarsine hydrochloride administered intravenously with or without bismuth gave disappointing results for although it shortened the attack it did not prevent relapses. In two patients penicillin was given—40 000 units every three hours for 60 doses a total of 2,400 000 units. Both

May 1948

Tropical Disease Bulletin.

were afebrile within 72 hours and showed no relapses. All the patients recovered without any serious complications incident to the disease or to the penicillin treatment. E Hinde.

HYND R. S. The Construction of Army Huts to Limit Infestation by *Ornithodoros moubata* (Relapsing Fever Tick). *East African Med. J.* 1945 Oct., v 22, No 10 337-42, 2 figs.

To investigate the possibility of constructing a tick-proof hut a series of experiments were conducted with *Ornithodoros moubata* to discover the climbing powers of the tick the conditions necessary to make the tick leave the floor to climb and if projecting metal strips in walls would act as barriers to climbing ticks.

The experiments were carried out in a specially designed wooden box fitted inside with two projecting metal strips to act as obstructions to ticks attempting to climb up the sides. A glass observation panel was provided in one side. A second box to hold a guinea pig was fitted into the top of the first. The experiments are described and from the results the author concludes that, in lightly infested huts there is little urge for ticks to climb the walls they will do so in heavily infested huts and in those with impermeable floors in order to find cracks the climbing urge is not influenced by the presence of a living being metal strips (rough or smooth) set into the walls and projecting from them do act as barriers.

Therefore he makes the following suggestions earth floors should be avoided as they are the normal habitat of *Ornithodoros moubata* a hard floor free from cracks can be made of latumen, concrete or beaten tar-and-earth it should be six inches thick and should have a metal strip inserted midway through its thickness and projecting three inches outwards all round. This will not, of course, prevent ticks being carried into the hut on the feet and clothing. A foot or so above the floor another metal strip should be inserted into the walls and this should protrude three inches all round the hut, both inside and outside. It is hoped that a test on a full scale model can be arranged, for if successful the decrease in the incidence of relapsing fever which could be expected if all huts were constructed in this manner might well be worth the additional expense involved in construction.

YAWS AND SYPHILIS.

DUVALIER, F. Contribution à l'étude du plan en Haïti. L'aspect médico-social et l'œuvre de la Mission Sanitaire Américaine. [Contribution to the Study of Yaws in Haiti. The Medical-social Aspect and the Work of the American Sanitary Commission.] Reprinted from *Bull. Assoc. Méd. de Langue Française de l'Amérique du Nord* L'Union Médicale du Canada. 1945 June v 74 20 pp 3 figs. 1 map & 1 chart. [37 refs]

Ninety per cent. of the Haitians are illiterate and 80 per cent. of the rural population is infected with yaws. Hygienic conditions are very poor and nutrition is defective. The interrelationship of ill-health and low economic output is stressed. Yaws is particularly prevalent in the mountainous rural areas where difficulty of access is a hindrance to effective treatment. Cases secondary and tertiary were more numerous during the rainy seasons. The author thinks that yaws was endemic before Columbus landed, and also that it was spread through the Slave Traffic. During the American occupation

1915-1924 anti yaws work was carried out and rural dispensaries were opened, but from 1931 to 1942 this activity practically ceased. In 1943 a further campaign was started by the American Sanitary Mission but it was considered that treatment alone was not sufficient and that an approach should be made along the lines of social medicine. Anti yaws centres were opened. Mapharsen (3 intravenous injections of 0.6 [presumably a misprint for 0.06 gm] at 8-day intervals) sulpharsphenamine and bismuth salicylate (3 intramuscular injections of 1.0 cc. [concentration not stated] at 8-day intervals) were used. The results with mapharsen were rather encouraging.

Although the social aspect is stressed the isolation and illiteracy of the population offer a tremendous barrier to any rapid achievement. Any plan for the eradication of yaws in Haiti should comprise a rational organization of the rural area with construction of new roads and repair of existing ones the establishment of a normal standard of living for the natives and the education of the 90 per cent. illiterate population which seems hardly to have emerged from slavery.

MONTEL R. Contribution à l'histo-pathologie de la lésion primaire d'inoculation et des lésions secondaires du pian. Chancres pianiques pianides pianomes [The Histopathology of the Primary and Secondary Lesions of Yaws.] *Bull Soc Path Exot* 1944 v 37 Nos. 3-4 71-84 8 figs on 4 pls & 1 text fig [23 refs.] C J Hackett

The author described in 1928 the primary lesion of yaws and contrasted it with the corresponding lesion of syphilis [see this *Bulletin* 1929 v 26 951] He later pointed out that contrary to the general view secondary lesions were not merely disseminated primary lesions but distinct. In the present article he takes up this question again. He has studied minutely the microscopic anatomy and histology of 6 primary yaws chancres 2 secondary rashes and 5 pianomas (generalized lesions) and he describes the histology of twelve of these in great detail. The contribution is illustrated by excellent photomicrographs depicting the changes which he describes. Those interested should consult the original description which is very condensed and to convey the details to readers would entail almost a *verbatim* transcription. As described in the letterpress the histological differences are quite marked. Briefly the primary yaw is characterized by ulceration which destroys the upper layers of the skin and presents at the border a marked hyperacanthosis with depigmentation. One photograph shows this clearly. The epidermis is invaded by motile cells in tracks and small groups displaced by oedematous areas. Beneath this migratory cells densely infiltrate with a conglomeration of polymorphonuclear cells plasmocytes lymphocytes histiocytes and many eosinophiles and in the deeper parts of the dermis is a certain degree of sclerosis. Giant cells are never present.

In the second group of lesions the pianides the epidermis is thickened but there is no hyperacanthosis the migratory cells penetrate at isolated spots only. Infiltration is not marked and is situated mostly round the cutaneous vessels and hair follicles and is made up of lymphocytes and histiocytes rarely any polymorphonuclears. Plasmocytes are absent. In the pianoma which is a papilloma without ulceration the hyperacanthosis of the epidermis is great the crust is stuffed with migratory cells which have traversed the infiltrated epidermal layers. A thick plasmocytic barrage is present the vessels are congested, new capillaries formed, stuffed with eosinophiles and swollen endothelial cells. There are no giant cells and no sclerosis of the deeper dermal layers. The rest of the article is taken up in stressing with quotations from the literature the tendency on the part of those working on the pathology of yaws to confuse these changes and it ends with a brief statement of certain differences

which distinguish yaws lesions from those of syphilis namely that the yaws lesions tend to be dermatropic that the infiltration is largely limited to the sub-papillary layer vascular lesions are slight, infiltration is not nodular and perivascular and the deep vessels are not affected. There are others but these are the chief
H Harold Scott.

MONTIEL, R. Les accidents secondaires cutanés du chan roséole pianides pianomes [Secondary Rashes in Yaws.] *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 5/6 137-45 5 figs (4 on 2 pls.) [15 refs.]

In the author's view too little attention has been paid to some of the cutaneous manifestations of yaws and the inexperienced are apt to regard them as new conditions and to give them a variety of names. He describes secondary lesions of the skin under four groups (1) *Roséola* fleeting and therefore often unnoticed, and hence not mentioned by some and denied by others. It appears most commonly about 20 days after the primary sore. (2) *Pianides* appearing in the interval between the roseola and the generalized eruption (which he calls pianomas). They always precede the general eruption but may continue to coexist with it. He speaks of four kinds of pianides (i) Furfuraceous circinate lichenoid or like pityriasis at one stage the condition resembles cutis asperna. The lesions are usually on the trunk, and cause considerable itching. (ii) Papular isolated or agminated papules in size from that of a lentil to that of a large pea buff or copper-coloured. They also cause itching, but usually regress spontaneously. (iii) Circular areas of desquamation erythematous and papulo-squamous on the palms and soles 1-2 cm. in diameter by fusion they may form curious geometric figures. (iv) Plantar hyperkeratosis often serpyginous and presenting a worm-eaten appearance. (3) *Mucosal lesions* on the lips and tongue in plaques resembling those of syphilitic leucoplakia, with well-defined border sometimes whitish or pearly or greyish yellow mammillated they may ulcerate. (4) *Pianomas* or vegetating papillomatous lesions oozing, but not desquamating. Of these also the author distinguishes four forms (i) Developing from the original yaw (ii) Resulting from transformation of one of his group 2 pianides (iii) The generalized yaws eruption (iv) The confluent condylomatous yaws.

Although these are all detailed as distinct they do not always remain so and one may pass into another the papular pianide (2 (ii) above) may become a papillomatous pianoma (4 (i) above) and the eruptive pianoma (4 (iii)) may become a vesicular papule or pustule (2 (ii)) but the author thinks it well to point out these various forms in order that their histopathology may be more closely studied. The article is well illustrated.

WHITEHILL, R. & AUSTRIAN, R. Further Observation on the Treatment of Yaws with Penicillin. *Bull. Johns Hopkins Hosp.* 1945 June v 78 No 6 274-94 10 figs

Forty-one Fijian cases of primary and secondary yaws in which spirochaetes were found and the Kahn test was positive are reported. The infections had been present 1-12 months and severe moderate and mild cases were about equal in numbers. Only eight patients had received any previous specific treatment, the maximum being "five injections of arsenic" 9 months previously. Thirty of the patients were under fifteen years of age. Penicillin was given intramuscularly in doses of 15 000 to 30 000 units at intervals of 3-4 hours to total dosages of 100 000 to 2 400 000 units.

In all cases except three no spirochaetes were found 16 hours after treatment had started and in those three no spirochaetes were found after 24 hours. No Herxheimer reactions occurred. In 37 cases healing was complete in three weeks despite differences in total dosage. In the other four cases the healing of single lesions about the ankle caused the delay. [Perhaps some other cause was present in all these cases.] The longest period of follow-up was 20 weeks (two cases) only 14 patients were observed for more than 10 weeks. In no case was a positive Kahn reaction permanently reversed, but no case receiving more than 1 200 000 units was observed for longer than 10 weeks. One clinical relapse after 230 000 units was observed nine weeks after admission.

The use of 100 000 units in four doses in 9-12 hours is probably as effective as many incomplete courses of arsenicals given over a longer period. It will cause the healing of secondary lesions and thus render the patient non-infectious at least for the time being. Further follow up work is being carried out at the Colomal War Memorial Hospital at Sava.

One case of tertiary yaws of five years duration in a child aged fifteen is reported. The skin and bone lesions responded more slowly but they had previously not healed despite prolonged and repeated arsenical and bismuth treatment.

GUMARÃES F N Penicilina pela boca Demonstração de sua atividade pela cura clinica da boubra (Nota prévia) [The Curative Action in Yaws of Penicillin taken by Mouth.] Hospital Rio de Janeiro 1945 Aug v 23 No 2 229-32 2 figs English summary C J Hackett

Demonstration of the activity of Penicillin by mouth was obtained by the clinical cure of three cases of yaws with primary and secondary lesions. The Wassermann reactions were negative in two cases after a month of observation but returned positive.

The treatment consisted in 1 000 O u by mouth diluted in water each two hours (excepted at 24 and 2 o'clock) during 10 days. The total amount of Penicillin per patient was 100 000 Oxford units.

LEPROSY

REVISTA BRASILEIRA DE LEPROLOGIA S Paulo 1945 Sept v 13 No. 3 133-227

The *Revista de Leprologia* in 1938 put forward the basis of a new clinical classification of cases of leprosy. In 1945 mainly at the instance of Dr Lauro de Sousa Lima doubts began to be expressed on the satisfactoriness of that classification and in view of the Pau American Congress of Leprologists which is to be held in Rio de Janeiro in 1948 the present is looked upon as a suitable time to reconsider the classification of cases of this disease.

This number of the *Revista* is devoted entirely to the subject. It opens with a reproduction of Dr Lauro de Sousa Lima's paper in which he stated that on certain points needing amplification or clarification in particular the difficulties in classifying the non-characteristic forms and those cases which undergo changes of type and intermediate relapsing cases. Examples are given where there is a conflict between the different factors of criteria in classification.

Thus (1) Cases clinically and histologically of the tuberculoid form but

BANCROFT H. GUIXTO R. S. RODRIGUEZ, J. V. & MARQUES A. P. A Note on Familial Relationship and the Risk of developing Leprosy *Internat. J. Leprosy* Cleveland, Ohio 1944 Dec. v 12 79-82.

In the Philippines the risk of infection of persons living in a house with a person suffering from lepromatous leprosy has been found to be eight times as great as that of those not known to have had such household exposure—these conclusions were formed on the basis of 283 families in Cebu Island P. I. with sufficiently complete records for analysis [this *Bulletin* 1936 v 33 931 1942 v 39 216 1944 v 41 48]. The duration of exposure to infection was expressed in person years—that is each year of life following exposure was counted as a year of risk. Only households in which the primary case was in a member of the family were included. The risk of infection from a neural case was no greater than for the general population. The highest rate of attack—4.31 per 1 000—was in a group exposed to an infected father—the rates in relation to mother, brother and sister varied between 3.57 and 3.60 only. The infection rates for males were always higher than for females except where the primary case was a mother—in that case the female rate was 8.10 per 1 000 against 1.95 for males—but that rate was based on too few cases (three females and two males) to be significant. Further inquiries on this important subject are needed. *L. Rogers*

MOISER, B. Modes of Transmission of Hansen's Disease (Leprosy) *Leprosy Review* 1945 Dec. v 16 No 2, 63-6

The author states that leprosy is undoubtedly a house or family disease yet in S. Rhodesia 60.9 per cent. of over 2,000 cases failed to give a history of contact with another case. At his hospital cockroaches have been investigated with the help of a trained hospital orderly who carried out microscopical examinations and found acid fast oval bodies in 69 per cent. of those obtained in the hospital or from kraals some distance away. Similar bodies were not found in other insects examined. They were also found in the dried droppings of the insects in which they survived for 169 days. He says that cockroaches bite man savagely at night but those caught in native huts and not fed on leprosy material also were found positive to "Hansen's bacillus". It is not stated on what ground the acid-fast bacilli in the cockroaches were determined to be those of Hansen but the author concludes that these investigations give some reason to doubt an exclusive contagion and infection theory of the transmission of Hansen's disease from man to man.

In an editorial it is recorded that Professor Buxton was consulted on this paper and he pointed out that cockroaches eat a great variety of types of food, and may be expected to swallow many types of bacteria, some of which may belong to the large group of acid fast bacilli which are therefore probably normal inhabitants of these insects. *L. Rogers.*

MONTEL, R. BRUX Mlle. & MARIANGEAS Mlle. La bacillémie lepreuse techniques de laboratoire pour sa recherche (Bacillæmia in Leprosy Laboratory Techniques for its Study) *Bull. Soc. Path. Exot.* 1944 v 37 Nos. 9/10 291-4 3 figs.

In this note the author deals with the methods of demonstrating lepra bacilli in the blood. He points out that the organisms are found in the large monocytes which are more numerous in blood taken from the ear under pressure, than in that from a finger. They may more readily be demonstrated in blood taken from a vein if 5 cc. are centrifuged after being received in a little citrate solution.

and if a preparation from the leucocyte layer is stained. Numerous bacilli are found in the protoplasm of the large monocytes and those free in the circulation are derived from ruptured leucocytes. L. Rogers

MON A M & BASOMBRIO G The Diffusion Factor in Leprous Skin. *Internat J Leprosy* Cleveland Ohio 1944 Dec. v 12 49-59 4 figs. on 1 pl [18 refs]

The diffusion factor dealt with by the authors is measured by injecting into the shaved skin of a rabbit a 1 per cent solution of trypan blue as an indicator together with the tissue extract to be tested and measuring the rate of diffusion around the site of injection. Testicular extract has the highest rate of diffusion. Tests have been carried out to compare the diffusion factor present in normal and in leprosy skins and it has been found that tuberculoid skin has a diffusion action nearly equal to that of normal skin but that the activity of lepromatous skin is considerably less and is similar to that of a saline control. The factor in skins containing different numbers of lepra bacilli were also measured and it was found that the diffusion activity of lepromatous skin is inversely proportionate to the amount of *Mycobacterium leprae* it contains. Further an extract of lepromatous skin appears to be antagonistic to the diffusion action of an extract of tuberculoid skin. [See also this *Bulletin* 1944 v 41 582] L. Rogers

TILDEN I L. Lepromatous Leprosy a Reticulo-endothelial Disease. *Histopathologic Aspects*. *Am J Clin Path* 1945 May v 15 No 5 165-77 12 figs [14 refs]

This is a detailed and well illustrated account of the microscopical characters of lepromatous lesions. The author supports the view of ASCHOFF regarding the reticulo-endothelial system which is especially involved in lepromatous leprosy with abundant lepra bacilli in the affected tissues and negative lepromin tests. The nodules are predominantly composed of histiocytes mostly spindle-shaped resembling fibroblasts. The epidermis over a nodule becomes atrophied and the papillary portion is often obliterated. When the tissue is stained with Sudan III there is a striking resemblance to xanthoma with varying amounts of lipoid material. Countless numbers of lepra bacilli are present, mostly arranged in parallel bundles. The globi are simply large or fused histiocytes forming giant cells. Another important feature is the absence of any necrosis such as is a typical feature of tuberculous lesions. The liver and spleen commonly show foci of similar involvement of reticulo-endothelial tissues with circumscribed milium lepromata most clearly seen in the liver. The lymph nodes are also affected with coarsely vacuolated cytoplasm. The glomerular tufts of the kidneys may show amyloid changes. The lungs are the least affected of the internal organs. Among 16 autopsies tuberculous complications of leprosy were found in 7. L. Rogers

DAVISON A R Notes on a Case of Lymphadenoma complicating Leprosy *Internat J Leprosy* Cleveland, Ohio 1944 Dec. v 12 38-40

The main interest in this case is that the development of symptoms of lymphadenoma in a lepromatous case in a European was followed by a remarkable change from repeatedly positive to repeatedly negative bacteriological examinations for lepra bacilli during the last two years of the patient's life. The treatment used at Pretoria was the usual one by subcutaneous and intradermal injection of chaulmoogra esters under which 20 to 30 per cent of the neural cases are discharged each year. In the case of lepromatous disease on the

with the organism of tuberculosis. To test this theory, the response of persons in non-endemic areas in the form of both early and late reactions has been tested. The results in ten patients with various dermatoses showed 9 early and 8 late positive reactions. Of four patients with Boeck's sarcoid, three gave negative results and one was weakly positive. At Seaview Hospital, New York, 108 patients with pulmonary tuberculosis were tested—the early (Fernandez) reaction was positive in 43 (70.4 per cent.) of 61 tested and the late (Mitsuda) reaction was positive in 50 (46.2 per cent.) out of 108. *L. Rogers.*

FENDEL, E. A. Leprosy. Initial Lesion and Surgical Cure. A Case Report. *Internat. J. Leprosy*, Cleveland, Ohio 1944 Dec. v 12 83-9

This paper records the present condition of two surviving leprosy patients in whom the primary lesion was removed surgically many years ago: they were first reported in 1937 see this *Bulletin* 1938 v 35 300. The first patient had voluntarily lived and worked in the Hawaiian leper settlement. In September 1932 he developed a solitary pink macule on his forehead and a second one a little later—in one of these the typical lepra bacilli were found in 1933 which did not produce any signs of tuberculosis or leprosy on inoculation into guinea-pigs. Histologically tuberculoïd changes were found in the excised lesions. Repeated subsequent bacterioscopic examinations have all been negative for lepra bacilli and he has remained free from other symptoms of the disease up to the present time eleven and a half years after the little operation.

The second case is in the female child of leper parents in Hawaii, both of whom had neural symptoms but she was removed from them at the age of six hours and brought up in a clean nursery (see GOODRICH & MCCOY this *Bulletin* 1916 v 8 243). While she was still an infant, a reddish brown nodule 12 by 8 mm. in extent and 2 mm. high on the flexor surface of the left forearm had been excised and a moderate number of lepra bacilli were found in it microscopically. The histology was entirely consistent with a leprous nodule. Seven months after the operation a few atypical acid-fast bacilli were found in a snap from the scar so she was declared to be leprous and continued to live in the settlement presumably with her leper parents. At the age of ten a careful examination failed to reveal any signs of leprosy—at seventeen she married a heavily infected lepromatous leper with marked nodules. In 1937 she applied for and obtained parole and was found, after thorough microscopical examination, still to be free from all signs of the disease. In 1944 she was again examined clinically and showed no evidence of leprosy so she has remained free in the disease for nearly thirty years. These cases afford a strong argument early diagnosis.

[It may also be pointed out that these cases strongly support the modern view that leprosy infection usually occurs through the entry of the causative bacilli into the skin through abrasions etc. including the punctures of insect bites to form at first an isolated local infection.] *L. Rogers*

MUIR, E. Preliminary Report on Diasone in the Treatment of Leprosy. *Internat. J. Leprosy*, Cleveland, Ohio 1944 Dec. v 12, 1-6.

In view of the favourable results of the use of the closely allied promin at the U.S.A. Carville settlement, and the favourable results reported from the administration of diasone in tuberculosis the latter drug has been tried by the author in lepromatous cases in the Trinidad Chacachacare Island leprosarium. Diasone was given intravenously in doses of 0.3 gm., the powder being dissolved or suspended in 1 cc. of sterile normal saline and the fluid filtered through three layers of sterile gauze. The injections were given six days a

week and the dose was gradually raised to 2-8 cc. In view of the anaemia producing action of the drug the dosage was controlled by watching the haemoglobin index. The early results—rapid clearing up of lepromatous ulcers and improvement in the general well being of the patients—inspired their confidence in the treatment but in some the appearance of anaemia and weakness led to the suspension of the treatment or a diminution of the dosage. Later the injections were restricted to three a week with dosage varying from 2 cc. to 8 cc. At first twelve cases were treated, but later the number was raised to about 100 in about half of whom the drug was given orally in capsules. If the haemoglobin fell below 78 per cent. ferrous sulphate was given orally. Beneficial results were noted in the form of general improvement in health, drying up of lepromatous ulcers and flattening of nodules, clearing of nasal lesions and of inflammatory eye lesions and disappearance of chronic fever and lepra reaction. Of 33 cases treated for over three months by intravenous injection 17 had greatly improved 15 were slightly improved and 1 remained stationary. Of 10 cases treated orally for over three months 7 had greatly and 2 slightly improved. In cases treated by either method for less than three months none showed great improvement but 36 out of 41 showed slight improvement. There was no evidence that changes in the haemoglobin content influenced the effects of treatment. Liver extract and iron in most cases improved any anaemia. The good effect in clearing up febrile and inflammatory symptoms was noteworthy. The results are therefore encouraging and are very similar to those produced by promin.

CHORINE V. Action thérapeutique du para amino-phényl sulfamide et de l'acétamide employés soit séparément soit associés dans la lèpre [The Therapeutic Action of Sulphanilamide and Acetamide separately and together, in Leprosy] *Bull Soc Path Exot* 1945 v 38 Nos 7/8 183-95

In this paper the author records experimental trials of acetamide and Septoplax [sulphanilamide] both separately and together with a control series in rat leprosy. Details of the experiment are recorded together with a table summarizing the results. Both local and generalized lesions were first produced by inoculating the rats with Stéfansky's bacillus and leaving them for the general development of the infection. The acetamide was given orally in solution in large doses over a period of 117 days. In a second series of animals large doses of "Septoplax" were administered for a similar period. In a third series both were given but the combination proved to be toxic and the animals wasted. Both drugs caused reduction in the local lesions at the sites of infection and prevented the development of lesions in the internal organs but no better results were obtained by their simultaneous use than separately.

L. Rogers

LENGAUER L. Palm Oil in Leprosy *Leprosy Review* 1945 Dec v 16 No 2 67-9

Working in the Benin province of South Nigeria the author heard of a leper village which had been founded by an ex leper. This man was found to have extracted oil from the kernels obtained from available palm trees and to have used the oil extensively by rubbing it into his skin. He soon noticed improvement in his health. To increase his food at low cost he had also drunk the oil to the extent of half a teacup at a time. At the end of a year he had recovered, and he then began to treat other leprosy patients in the same way, and soon a village had grown around his solitary hut. At the time of the visit

of the lady doctor the village was very clean and about 100 lepers looked well. They showed peculiarly smooth skins and tuberculous areas and macules seemed to be flattened, as if almost dissolved although no other treatment had been given. Only lepers from neighbouring villages were admitted. The author decided to try palm oil treatment herself and she found that chronic ulcers did very well under an ointment composed of zinc oxide powder mixed with palm oil. This oil, given orally in place of cod liver oil during the war was also beneficial, and relieved constipation. It is a cheap method of supplementing a deficient diet.

FAGET G. H. & FOGGE R. C. Penicillin used unsuccessfully in Treatment of Leprosy *Internat J Leprosy* Cleveland, Ohio. 1944 Dec. v 12, 7-10

This short note records the trial of penicillin in seven lepromatous or nodular cases of leprosy with negative results as regards the primary disease. Two of them showed recently developed nodules the third was a specially early case and the other four had more or less advanced lepromatous lesions. Complications included eye, nasal and laryngeal lesions. No beneficial effects were observed in these conditions with the exception of healing of secondarily infected ulcers in one case. The doses of penicillin used were up to 50 000 to 100 000 units daily for a period of several weeks. In an addendum written six months later the authors report that during that time no beneficial result attributable to the treatment had been observed in the seven cases first treated. Four others treated with much larger doses had also failed to respond to penicillin.

L. Rogers.

SLOAN N. R. Tracheotomy in Leprosy *Internat J Leprosy* Cleveland, Ohio. 1944 Dec. v 12 11-30 6 figs.

This paper deals with an extensive experience in advanced lepromatous cases at the Hawan Molokai settlement, where no less than 13.1 per cent. of "active patients" are wearing tracheal tubes. During a twelve-year period, 148 tracheotomy operations have been performed on 144 patients. Information is tabulated on the time from first isolation to operation and age at time of operation. Leprotic laryngitis is found only in lepromatous cases and it commences with great thickening of the epiglottis. Spread of the disease to the vocal cords produces stenosis requiring operative relief. Increasing hoarseness and dyspnoea, with choking spells are the main indications for the operation, which should not be delayed too long.

The surgical anatomy and operative procedure are fully described. After the operation a semi-sitting position for a day or two, codeine sulphate in half grain doses orally before meals for three days and liquid diet for a day or two are advised. Later the tube should be removed for cleansing twice a day. Relief is quickly afforded. Out of 98 cases tabulated, 14 deaths are classed as post-operative within two weeks and of the remaining 84 28 are classed as "tube deaths" in the sense that they were indirectly caused by the laryngeal lesion which necessitated the operation. The deaths from tuberculosis were only 15 to 18 per cent. about half the rate for the settlement at large. Those still living number 48 one of whom has worn a tube for six years.

Dow D. Occupational Therapy in Leprosy Institutions. *Leprosy Review* 1945 Dec. v 16, No. 2, 57-63.

The author writes from experience at the Dichpali Leprosy Hospital, India, in which there are 800 resident patients, mostly men. He first stresses the

importance of studying the psychology of the patient as he holds that few if any of the patients are really healthy minded. The patient's sense of frustration should be removed and he should be helped to resume his place in society for which purpose he should be provided with suitable occupation and work of a useful nature to restore his self-confidence. Active outdoor agricultural work is best for those fitted for it but for others cooking and the preparation of grain etc. house cleaning the grinding of rice and flour are suitable occupations. It was not found possible to make weaving profitable. Women are employed in washing and mending clothes cooking light gardening etc. The older children do similar work to that of the women except for cooking. Each patient on admission is given a labour classification.

The original 50 acres of the colony have been increased to 450 acres of these 250 are devoted to agriculture with the help of irrigation from a tank and wells. The products are of financial importance but of more importance is the satisfaction and contentment of the patients as the result of doing interesting and productive work.

LEPROSY REVIEW 1945 Dec. v 16 No 2 40-57 Preventoria. A Symposium on the Care of the Children of Leprous Parents.

The important subject of the best methods of protection from infection of children born to leper parents is summarized in an introduction by the Editor Dr E. MUIR. This was sent to several experienced workers for their comments which are recorded in this important article. The principles discussed are that children are specially susceptible to leprosy and should be separated from infective parents as soon as possible after birth. To effect this either the infected patient may be isolated or the child removed to the care of relatives or to a preventorium for such children usually under the care of missionaries as in India. It is easier to make such provision in a wealthy country like Brazil with its 22 preventoria than in poor countries. In Nigeria the position is difficult and the rearing of children apart from their parents is injurious to them for crèches in the tropics are very difficult to run efficiently.

In commenting on the above statement Dr MONEY of Nigeria thinks that closed cases are not dangerous even to infants at the breast. He agrees on the danger of rearing infants artificially in the tropics and in general with the principles under discussion. Where practicable the use of wet nurses is beneficial. Four years' experience of allowing closed cases to retain their children has justified itself.

Dr DAVEY also of Nigeria is in agreement with the principles. He tabulates information on 3 031 uninfected children of leper parents. The type of leprosy to which 1,935 children actually living with an infected parent were exposed was—active lepromata in 128 early lepromata in 261 simple neural leprosy in 576 tuberculoid leprosy in 977 in 43 the type was unstated. This constitutes a serious problem, for the cases dealt with form only about one-fifth of those of the province of Owerri and work on a large scale is necessary to prevent child infections by making suitable provision for the separate accommodation of children of parents with open leprosy. Weaned children should be sent to healthy relations and should be examined periodically. A small crèche is necessary to accommodate new-born children of lepromatous women in settlements.

Dr ROSS of Southern Nigeria, in a short note agrees with Dr Davey. Dr WHARTON in British Guiana has little difficulty as the sexes are separated at the Mahaica leprosy hospital and the few infants born are taken over by a relative or guardian usually within seven days of birth. Dr Robert COCHRANE in Madras recognizes the importance of the problem but in India, in the case of nearly all the children exposed to serious risk of infection relatives can usually

be found to take charge of the child, or the lepromatous parent can be isolated. There is still scope for healthy children's homes. Cochrane also advocates the separation of children from night contact with an open case in villages—there is evidence that this procedure produces good results.—

Lastly Dr John LOWE, of Calcutta, is in agreement with the above opinions, and as a result of his own experience emphasizes the danger of children remaining with leprosy parents even for 18 months from birth, for a number of them (25 of which are tabulated) developed signs of the disease later and had to be removed from healthy children's homes. He therefore advises the early adoption of infants by healthy relatives.

HELMINTHIASIS.

SAUTET J & MARNEFFE H. Infestation naturelle de *Planorbis aduncus* Bourguignat 1879 par *Schistosoma mansoni* au Soudan Français. [Natural Infestation of *Planorbis aduncus* by *Schistosoma mansoni* in the French Soudan.] *Bull Soc Path. Exot.* 1944 v 37 No. 9/10 320-21

In 1942, in the area of Baguineda, near Bamako French Soudan, where the villagers were heavily infested with rectal schistosomiasis snails of the species *Planorbis aduncus* were found naturally infested with fork-tailed cercariae. Mice were infested by placing them in water containing the cercariae and adult *S. mansoni* and their eggs were recovered from the mice especially from the liver

J F Corson

HERNÁNDEZ MORALES F. The Treatment of Schistosomiasis. *Puerto Rico J. Pub. Health & Trop. Med.* 1945 Mar v 20 No. 3 322-33. [Refs. in footnotes.] [Spanish version 339-56.]

After a "partial review of the literature" on the treatment of schistosomiasis with emetine and with antimony in its various forms there follows "an analysis of one hundred and fifty-seven cases of Schistosomiasis mansoni treated with Fouadin." The occurrence of this infection has become more prominent during the last few years in Porto Rico. Many persons are unaware that they harbour the infection and a large number of apparently healthy youths were rejected for military service on account of it. The disease now constitutes a public health problem of first importance to Porto Rico. Fouadin has been widely used in treatment with conflicting local views on its efficacy up to now there has been no proper analysis of the results of its employment. A cure rate of between 50 and 60 per cent. was obtained with Fouadin by the author after one or more courses of treatment of his cases. This is in accord with the experiences of others elsewhere. The criteria of cure were the disappearance of symptoms of eosinophilia and of ova from the stools. Ova usually vanished between the fourth and twenty-fifth days (usually by the thirteenth) [whether from the beginning or after the completion of the course of drug treatment is not clear]. Toxic reactions caused by Fouadin were encountered, and in some cases were regarded by the author as severe.

A R. D. Adams.

LAVIER G & STEFANOPOULO G L'intradermo-réaction et la réaction de fixation du complément dans la distomatose humaine à *Fasciola hepatica* [The Intradermal Reaction and the Complement Fixation Reaction in Human Fascioliasis caused by *Fasciola hepatica*] *Bull Soc Path Exot* 1944 v 37 Nos. 9/10 302-8 [21 refs.]

The authors review many earlier papers in support of their view that contradictory statements occur in the literature about the value of the complement fixation reaction for the diagnosis of human fascioliasis. This review is useful because some of the papers summarized in it are not easily accessible or are not often quoted.

For their own work the authors prepared an antigen by Fairley's method, which was also used by STEFANOPOULO and PAYET (*Gaz méd de France* 1938 No 6 315) and for the preparation of filarial antigen by STEFANOPOULO and DANIAUD [this *Bulletin* 1941 v 38 156]. *Fasciola* obtained from the slaughter house were dried and powdered. One gramme of this powder was kept in 100 cc. of physiological saline at 37°C. for one day and the supernatant fluid was filtered through a Seitz filter. For use it was diluted 1/4 or 1/5 or more. This antigen gave immediate intradermal reactions. After 3 to 5 minutes a weal with pseudopodia appeared which reached 3 cm. in diameter erythema appearing later. One or two hours later both erythema and weal disappeared, but infiltration of the skin and tissues around the reacting area persisted for 4 to 6 hours. After 24 hours the reaction had disappeared entirely. Delayed reactions were not observed but some strongly positive subjects showed delayed phenomena such as generalized urticaria, pain and swelling of neighbouring articulations. Two subjects showed nausea, profuse diarrhoea lasting several hours, lipothymie and signs of shock. Subjects sensitive to various proteins may give false positives but their reactions are usually surrounded by a smaller erythematous halo not more than 1 cm. in width which disappears very quickly.

For the complement fixation reactions the authors used powdered *Fasciola* 1 gramme of which was kept in 100 cc. of absolute alcohol at 37°C. for 24 hours, filtered and then evaporated until when it was evaporated to one-third of its volume it usually became cloudy. Absolute alcohol was then added to the initial volume and the precipitate disappeared. This final solution formed the antigen. It was usually active at a dilution of 1/20.

The sera of five subjects affected with fascioliasis were used. The first had had fascioliasis for ten years, the second had contracted it ten years before but was clinically cured and six months earlier the stools contained no eggs of *Fasciola* and there was no eosinophilia. The third had had fascioliasis for ten years, this subject was described by DALLAINES, LAVIER and GANDEILLE [this *Bulletin* 1943 v 40 472]. The fourth had had fascioliasis for 3 years but only a few eggs of *Fasciola* were present in the stools. The fifth had had fascioliasis for 4 months and the positive intradermal reaction obtained was temporary with the appearance of eggs of *Fasciola* in the stools. The controls were (1) the sera of 3 subjects infested with *Loa loa*, the infestation of one had lasted 6 years, that of another 7 years and that of the third 4 years. (2) the serum of one subject harbouring *Taenia saginata*, this subject had been treated for this condition the day before the tests were done. (3) the serum of one subject harbouring *Echinococcus* cysts. (4) two subjects serologically proved to be suffering from syphilis. (5) the sera of 3 subjects without evidence of fascioliasis, no eggs of *Fasciola* were found in the stools of these three subjects after repeated examinations but one had an eosinophilia of 50 per cent, another a moderate eosinophilia and the third the normal number

May 1946

of eosinophils. Tests done with a filarial antigen and *Echinococcus* fluid showed that the controls with these infestations were positive to these antigens. A table gives the results. It shows that the *Fasciola* antigen was specific. All five subjects tested gave positive intradermal and complement fixation reactions to the *Fasciola* antigen and all were negative to the filarial and *Echinococcus* antigens except the subjects infested with these helminths. None of the controls reacted to the *Fasciola* antigen. The authors remark on the fact that the two syphilitics were negative to it although it has long been known that syphilitics may give a positive complement fixation reaction to helminth antigens. They quote several papers which record this fact but point out that FAIRLEY showed that a suitable dilution of the antigen avoids false positives due to syphilis. The authors could not obtain a bacterial antigen but suggest that this antigen might give positive results with sera of subjects of fascioliasis because *Fasciola* and *Schistosoma* are nearly related. They suggest that the discordant results obtained by earlier workers may have been due to variations in the method of preparation of the antigen and to the fact that most of the infestations to which the authors refer were done upon sheep which often lose their reactions but retain antibodies when no flukes can be found in them. One of the human subjects tested by the authors had very strongly positive intradermal and complement fixation reactions although he had been for some months clinically cured. The implication presumably is that this subject had retained antibodies in his blood during this period.

MARTIN R. LE ROY SIREAU B BABOUCOT P & BOURCART N. Un nouveau cas de distomatose hépatique diagnostic précoce par le tubage duodénal. (A New Case of Hepatic Fascioliasis early Diagnosis by Duodenal Intubation.) Bull Soc Path Exot 1944 v 37 Nos. 11, 12 359-63 2 figs. [15 refs.] G. Lafage

The authors say that cases of hepatic fascioliasis have increased in numbers during recent years in France. They mention epidemics at Clermont Ferrand and Lyons. They think that, when a febrile syndrome with marked eosinophilia is encountered, every effort should be made to exclude fascioliasis. Early diagnosis is important because treatment with emetine is especially effective when the flukes are young.

The authors describe the case of a girl, aged 14 who was admitted to hospital with persistent fever lasting a month and a half. The history showed that three months before admission while the girl was on holiday in the country she complained of continuous headache pain in the right hypochondrium and at times bilious vomiting. On her return to Paris the pain and vomiting had ceased but the girl was thin and had no appetite. Tuberculosis and typhoid infection were eliminated. The liver was painful and enlarged. Painful crises occurred which resembled hepatic colic. The spleen was palpable and there was slight xerema. Other examinations were negative except that the blood showed an eosinophilia of 46 per cent. Hodgkin's disease was eliminated by sternal puncture and the Gersoni and Weinberg reactions for hydatid disease were negative. Duodenal intubation then revealed the presence of eggs of *Fasciola* and examination of the stools subsequently also revealed them. The patient said she had never eaten water-cress (oregon) but she was very fond of eating herbs picked casually during her walks. She was treated with emetine. (The doses given are not stated.) The number of eggs in the stools became smaller and smaller until none was found. The eosinophilia decreased to 20 per cent. but duodenal intubation still revealed eggs of *Fasciola* in the duodenum. A month later two duodenal intubations failed to reveal eggs. The authors remark that the painful enlargement of the

liver which is one of the cardinal symptoms of fascioliasis was absent from this subject the hepatic symptoms were only transitory. The patient however did show a symptom rarely recorded in subjects of fascioliasis namely enlargement of the cervical lymphatic glands. The palpable spleen is emphasized by the authors but this is an exceptional sign. They remark that the coexistence of an irregular temperature with profuse sweats and a high eosinophilia suggests fascioliasis. Duodenal intubation enabled them to diagnose the disease in this subject during the acute hepatic phase during which young flukes enter the liver before eggs of *Fasciola* appear in the stools. After this stage the subject often gets better and the infestation becomes chronic. In literature supplied to the authors by Professor LAVIEZ only 6 out of 127 cases were diagnosed during the acute early phase. Duodenal intubation can establish the diagnosis 15 days before eggs of *Fasciola* appear in the stools, so that emetine, which kills the young flukes more effectively than the older ones can be given.

ZAFHAROV V. I. [To the Epidemiology of the Alveolar Echinococcosis in Kazakhstan.]
Med. Parazit. & Parazit. Dis. Moscow 1945 v 14 No 4 33-4 [In Russian.]

SCOTT J. A. Hookworm Disease in Texas. *Texas Reports on Biol. & Med.*
 1945 v 3 No 4 558-68 1 fig. [14 refs.]

The available data indicate that in most of the parts of Texas where hookworm was once common the infection now occurs only in a very small percentage of the population and clinical cases are a rarity. In a small area in the extreme eastern part of the state the infection is more common but even there it is not more than half as frequent as it once was. A rough estimate based on the meager information available indicates that probably not more than 10 000 persons are infected and the number of clinical cases probably does not exceed 1 000. The improvement over conditions known to exist 30 years ago has probably been due in part to the control programs of various sorts. On the other hand in spite of depression set backs there has been a general lifting of the economic level of living in these areas which has undoubtedly been reflected in the decrease of hookworm prevalence through improved nutritional and sanitary conditions. There is a great need for further investigations to determine the exact public health status of hookworm disease at the present time and to define the conditions which might be modified so as to effect further control.

FISCHER F. K. Beitrag zur Kenntnis der Anguilluliasis oder Strongyloidosis
 [Contribution to our Knowledge of Anguilluliasis or Strongyloidosis.]
Schweiz. med. Woch. 1946 Feb 16 v 76 No 7 137-40 1 fig. & 1 chart.
 [21 refs.]

The author states that the records of strongyloidiasis particularly reports on it in the German Ruhr district show that it often co-exists with hookworm infestation. He briefly outlines the life-history of *Strongyloides stercoralis* and reminds us that auto-infection can maintain an infestation the skin-penetrating larvae being able to develop either in the large intestine or in faecal matter adhering to the anal region and to penetrate either the mucosa of the large bowel or the perianal skin. The author states that few clinical papers report strongyloidiasis as a serious disease, although ASKANAZY (*Cent. f. Bakt.*, 1 Abt. Orig. 1900 v 27 569) found in sections of the upper part of the duodenum and in the ileum severe damage done by the larvae which burrow into the mucosa of these parts of the intestine. The severity of any helminth infestation is however affected by the numbers of helminths present.

May 1946

The author reports in great detail his study of one patient infested with *S. stercoralis*. This patient was an Australian infantryman born in 1919 who had served in Palestine and Greece and had been captured in Crete in 1941. An epidemic of diarrhoea broke out in the unhygienic prisoners' camp in Crete and the patient was severely ill in hospital. Transferred to Salonika and later to Athens, he suffered repeated attacks of severe diarrhoea and abdominal pain with flatulence. Treatment [unspecified] was given for dysentery and living in Athens for a time he was fairly well until in June 1942, to Italy where he was fairly well until in June 1942 he had another attack of diarrhoea, abdominal pain and flatulence lasting five weeks. He was again fairly well until June 1943 when the same symptoms recurred. In that year he reached Switzerland where in October 1943 he developed cough, sore throat and a rash resembling sudamina. Suspected of having measles he was sent to hospital where he had an attack of diarrhoea with blood and mucus in the stools and abdominal cramp. Examination revealed little likely to account for his illnesses. On October 20 1943 a differential leucocyte count showed that there were 54 per cent. of eosinophils in his blood. Agglutination tests ruled out typhoid, paratyphoid bacillary dysentery and brucellosis. The bloody diarrhoea continued, but the rash disappeared. On October 25 there were 18 per cent. of eosinophils in his blood. Neither *Entamoeba histolytica* nor its cysts were found in the stools, but these did contain larvae of *S. stercoralis* and eggs of *Ascaris* and *Trichuris*. On November 1 the subject was much the same and "Chenosis" expelled 5 *Ascaris*. There were then 32 per cent. of eosinophils in the blood. On November 6 there were 40,000 white blood cells of which 72 per cent. were eosinophils. Bone marrow obtained by sternal puncture revealed a very greatly increased formation of eosinophils. [Details of the differential counts of blood and bone marrow cells are given.] On subsequent dates the eosinophilia was as follows: Nov 8 77 per cent. (i.e. 3,000 of 40,000 white blood cells); Nov 9 77 per cent. (i.e. 3,000 of 40,000 white blood cells); Nov 12 81 per cent. (i.e. 18,900 of 23,400 white blood cells). From this date this very high eosinophilia gradually decreased and with its decrease the patient felt much better and the diarrhoea ceased. On December 24 however the subject had marked pain in the penis and perineum with small haemorrhages from the urethra and swelling of the corpora cavernosa extending back to the perineum. There were very painful erections and reddening of the skin on the under side of the penis. The white blood cells rose from 9,800 to 16,000 with 41 per cent. of eosinophils. This condition disappeared in three days. By January 12, 1944 no larvae of *S. stercoralis* were found in the duodenal contents. The patient left for Australia with an eosinophilia of 35 to 45 per cent. A subsequent message from Australia said that he had felt well until February 1945 but still had larvae of *S. stercoralis* in his stools.

Discussing this case the author points out that *Strongyloides* can be distinguished from hookworm in the fact that its eggs are never found in the stools they can only be obtained either by a very drastic purge or by duodenal intubation, and then are seen to be always embryonated while the eggs of hookworms are not. The author never found the filariform larvae of *S. stercoralis* may cause sensitivity of the skin so that itching and the formation of weals may occur in the perianal region. A condition resembling "creeping eruption" may be established, and FULLEBORN (*Ann. Wack.*, 1925 v 35 1709) described the formation of similar weals on the skin of subjects infested

with *S. stercoralis* after injection into the skin of an antigen made from dried and powdered *Strongyloides* larvae. The urethral haemorrhages and the pain and itching of the penis of this patient are ascribed by the author to this cause. When the patient washed these parts with soap and applied 10 per cent. *Ung. Hydrarg. praec. alb.* these symptoms did not reappear [cf. the infestation of the genito-urinary tract with *S. stercoralis* described by WHITEHILL and MILLER, this *Bulletin* 1945 v 42 576].

Enormous eosinophilia such as that here recorded is unusual. It has been ascribed to an allergic condition in subjects with an eosinophil constitution, but FISCHER suggests that in this patient a toxic effect was responsible. The patient was treated for 9 months but both adult *Strongyloides* and its larvae remained. He was however in good health, when he had an eosinophilia of 30 per cent. and larvae were not so numerous in his stools after treatment.

Gentian violet in doses of 6×0.04 g. daily for about 3 months produced no improvement; larvae remained in the stools. Gentian violet was therefore combined with the following additional treatment which was given at the same time. The patient was prepared with a saline purge. In the forenoon he had an enema of 1 per thousand thymol solution or benzine water and on the following morning oil of chenopodium (two doses of 18 drops with 1 hour's interval between) followed at intervals of one hour by three doses of one teaspoonful of sulphur depuratum. In the resulting diarrhoea massive numbers of dead *Strongyloides* larvae were found. This treatment was given 3 times at intervals of 8 days at the same time as the gentian violet and it produced no untoward results. No better results were obtained with filix mas, santonin or thymol. Carbon tetrachloride, tetrachlorethylene, atabrin, intravenous neosalvarsan, intravenous arsacetin, kamala, areca seed and Fouadin were all ineffective. Phenothiazine was also ineffective and had to be given up on the seventh day because it caused the excretion of porphyrin. A final attempt to cure the subject by duodenal intubation of 1 per cent. aqueous solution of gentian violet caused nausea, vomiting and collapse and the subject's departure to Australia prevented further trials of it. The author says that he gave in this way 250 cc. of the 1 per cent. solution of gentian violet at the rate of 50-60 drops a minute. [CRAIG and FAUST *Clinical Parasitology* 3rd edition 1943 253 recommend 25 cc. See also v ENGEL, this *Bulletin* 1945 v 42 49 who also began with 250 cc. but because of its severe effects substituted 100 cc. at a slower rate and claimed to have cured his subject. See also the other references mentioned in this abstract and PALMER this *Bulletin* 1945 v 42 135.]

DROUET P. L. THOMAS C. HERBEUVAL R. & FAIVRE G. Hémorragies du vitré et ascariidose. Nouvelles hémorragies du vitré et néphrite consécutive à une intradermo-réaction à la toxine ascaridienne. [Haemorrhages of the Vitreous and Ascariasis. Fresh Haemorrhages of the Vitreous, and Nephritis, following an Intradermal Reaction to the Ascarid Toxin.] *Bull. et Mém. Soc. Méd. Hôp. de Paris* 1945 Nos. 24/25 342-4.

The authors describe the occurrence of bilateral haemorrhages into the vitreous humour of the eye of a woman aged 60. Clinical examination revealed nothing likely to account for these but the blood contained 22 per cent. of eosinophil leucocytes and about a year later when the haemorrhages recurred 18 per cent. of eosinophils. The stools contained eggs of *Ascaris* and *Trichuris*. Santonin at first failed to expel any nematodes (perhaps because the doses were too small) but later it expelled some ascarids. The eosinophilia persisted. The authors discuss possible causes of the haemorrhages but come to

the conclusion that they were associated with the ascariasis. Haemorrhages in the course of ascariasis have been noted by CASSOUTE and VAGUE (*Soc. Péd.* 1934 Jan. 16) MATHIEU and FAIVRE (*Soc. Méd. de Nancy* 1945) reported repeated haematuria coinciding with the expulsion of an *Ascaris* through the mouth but haemorrhages of the vitreous have been still more rarely reported in subjects infested with various parasites. In this subject however the eosinophilia persisted. The complement deviation reaction failed to reveal the presence of antibody in the blood, but this was not surprising because this antibody appears the authors state only when the cuticle of the nematode is ruptured or its permeability is altered by its death (*cf* hydatid cysts). The authors did intradermal reactions on this subject with the dilute coelomic fluid of *ascaris* derived from the subject under consideration. With a dilution of 1/100 of this fluid they obtained on two separate occasions a non-pruriginous papule the size of a 50 centime piece which appeared in a few minutes and disappeared after 1 hour. The same test gave the same result two days later. Two days later still a test was done with "Ascaris toxin" [the precise method of preparation of this is not stated]. Almost immediately this "toxin" produced a non-pruriginous cockade reaction 2½ cm. in diameter with a haemorrhagic centre and erythematous periphery sprinkled with petechiae and an intermediate zone. A control intradermal reaction on a subject also infested with *Ascaris* but without any signs of similar haemorrhages into the vitreous produced in half an hour a non-pruriginous erythematous weal which disappeared in three-quarters of an hour. In several subjects not infested with *Ascaris* neither early nor delayed reactions were obtained.

About 4 hours after the intradermal reaction the subject under discussion showed a renewed haemorrhage in the temporal region of the right eye. She complained of lumbar pain. Next morning there was palpebral and malleolar oedema. The urine contained albumin, granular and hyaline casts, renal cells, red blood cells and polymorphonuclears. There were no other clinical symptoms. Two days later the oedema had disappeared. The urine contained a few erythrocytes and less albumin and urea but no casts. There was a blood eosinophilia of 10 per cent. Some days later the subject went home without any trace of nephritis.

The authors thus obtained experimental proof that *Ascaris* toxin was the cause of the haemorrhages into the vitreous of this subject, but the nephritis and haematuria were new factors. The authors ascribe it not to an anaphylactic reaction, but to what TZANCK has called renal intolerance. It resembles allergic nephritis. The intradermal reaction done with "Ascaris toxin" precipitated in this previously sensitized subject a true phenomenon namely a local haemorrhagic crisis which became general and attacked the eye and the kidney in which there was a temporary allergic haemorrhagic nephritis. We know that certain organs and especially the kidney are apt to show haemorrhagic reactions. Perhaps there was some individual cause in this subject to explain the localization of the haemorrhages in the eye.

Among authors who have studied the intradermal reaction to *Ascaris* "toxin" are CIRCULESCU (*Soc. Méd. des Hôpitaux de Bucarest* 1927 April), AVRAMOVIĆ and DANCILLA (*Rev. Péd. et Pédiat.* 1937 December) and SIMONIN (*Thèse Nancy* 1919).

THOMPSON K. J., RUFEN H. & ZARROW M. Early Filariasis in Young Soldiers. Clinical and Pathologic Analysis. *J. Amer. Med. Ass.* 1945 Dec. 15 v. 129 No. 16 1074-9 [13 refs.]

A series of 200 young American soldiers infected with filariasis [presumably Bancroftian] has been studied during a period of two years. As a result of

prolonged clinical observation with biopsies of superficial lymphatics or lymph glands and the employment of a skin test using for this a *Dirofilaria immitis* antigen in various dilutions a concept of the pathology of early filariasis has been elaborated. The early stages of the disease are very different from the later classical elephantoid stage described in textbooks. After describing the six clinical groups into which their cases fall the authors conclude that there is no one symptom or sign that is constantly found in all cases of the early disease other than persistently enlarged and palpable lymph nodes. These in the earliest acute phase are large and soft but later they shrink and become hard. The differential diagnosis of the gland enlargement of early filariasis is dependent on biopsy of lymph cords and lymph glands and on the employment of the skin test described in detail by the authors. The biopsies were performed on superficial lymphatics and glands and where funiculitis was present material was taken from the pampiniform plexus under local anaesthesia. In the examination of lymph glands the authors found that the axillary glands were more likely to give a distinctive microscopic finding than the inguinal glands and they warn against the obvious temptation to take the latter purely on account of easier accessibility. They regard the lymphatic involvement during the first phase of the early stage of the disease as systemic rather than focal in origin and prefer to examine a lymphatic cord or gland bizarrely situated as long as it shows evidence of acute involvement. There is little to be learned from the incidence of primary lymph gland involvement. As a result of their studies they conclude that early filariasis can be divided into three phases—(a) the early acute or allergic (b) the subacute (c) the early chronic as follows—

(a) The *early acute phase* is characterized clinically by sudden lymphangitis with an accompanying lymphadenitis of the regional lymph glands lasting for 3-4 days. Fever and constitutional upset are minimal. Though the lymphangitis extends as a rule in the normal direction in some cases it is retrograde or centrifugal in its extension. The attacks may recur over 8-9 months or they may be single events. At the height of the lymphangitis in the arm leg or structures of the cord there may be lymphadenitis and lymphangitis bizarrely situated elsewhere. Funiculitis and epididymitis were seen in about half the cases usually these are unilateral although succeeding attacks may involve the opposite side they may subside rapidly with the declension of the lymphangitis. In association with them the inguinal glands are slightly enlarged and there is commonly an associated small hydrocele and a brawny oedematous thickening of the scrotum. The cord may become as thick as the thumb and the vas deferens as thick as a lead pencil.

During this stage no microfilariae are to be found in the blood even when a concentration technique (Knott's) is used. Eosinophils are slight or moderate. Biopsy shows hyperplasia of the lymph follicles with eosinophilic infiltration and general oedema of the lymph glands. In many cases filarial worms are actually to be seen in the gland but the pathological picture apparently is not dependent on the visible presence of the worms. Lymph glands remote from the site of the lesion and containing no worms or microfilariae show similar pathological changes—thus supporting the view that the changes are of a generalized systemic nature and not purely focal.

Biopsy of an acute filarial lymph channel shows thickening oedema and eosinophilic infiltration of the wall. The lumen is filled with an acute thrombus in which the eosinophils are pyknotic and aggregated into a necrotic amorphous mass. Filarial worms or microfilariae may or may not be seen in the lymphatic vessel.

(b) In the *subacute phase* there is no lymphangitis swelling or oedema but a feeling of heaviness and aching of the involved part is experienced with little

cent. (38 out of 40) subjects without microfilariae were positive to a dilution of 1:10,000 of the *D. immitis* antigen. The percentage of positives and negatives to the other dilutions of the various antigens was of the same order.

With regard to cross reactions with other nematodes the authors found that among the 180 subjects in group A 127 (70 per cent.) had either *Ascaris Trichuris* or "hookworm" i.e. 68 (75 per cent.) of the 90 with microfilariae in their blood and 59 (66 per cent.) of the 90 without microfilariae. None of group B however had intestinal nematodes. All the subjects in group B were negative to dilutions of 1:200 and 1:10,000 of the three filarial antigens except two subjects (12 per cent.) who gave positive reactions to *Ascaris* antigen and also to physiological saline. The authors think it unlikely that these two positive subjects were suffering from early or low-grade infestations. They point out that CULBERTSON, ROSE and DEMAREST (*loc. cit.*) and BOZICEVICH and HUTNER [this *Bulletin* 1944 v 41 1055] also obtained negative reactions to 1:200 and 1:8,000 dilutions of rat and dog filarial antigens in Americans not infested with nematodes.

These results suggest that skin reactions to filarial antigens may be greatly influenced by the presence of other nematodes. The presence of group-specific substances is also suggested by the fact that 85 per cent. (17 out of 24) of subjects in group A without microfilariae in their blood gave positive reactions to 1:10,000 dilutions of *Ascaris* antigen and 75 per cent. (15 out of 20) of subjects with microfilariae gave positive reactions to 1:10,000 dilutions of hookworm antigen. Similar results were obtained in those members of group A who had no microfilariae in their blood. The authors think that subjects with any of the nematodes may become skin sensitive to antigens from any member of the group. They refer to BACHMAN and RODRIGUEZ MOLINA [this *Bulletin* 1933 v 30 222] who reported positive skin reactions to hookworm antigen by subjects without hookworm infestation but with infestations with *Ascaris* and *Trichuris* to RODHAM and DUBOIS [*ibid.* 1932, v 29 83] and BRUNNER (*J. Immunology* 1933 v 15 83) who found that *Ascaris* antigens give positive reactions when other species of nematodes are present and to MAZZOTTI and OSORIO [this *Bulletin* 1944 v 41 957] who obtained 13 per cent. of positive reactions to *Onchocerca caecutiens* antigen by subjects not infested with this species.

The percentage of positive reactions obtained by the authors to the 1:10,000 dilution of *Dirofilaria immitis* antigen in the Porto Ricans of Group A, namely 87 per cent. far exceeds the estimated percentage infestation of the general population of Porto Rico namely 9.7 per cent. recorded by HOFFMAN, MARIN and BURKE [this *Bulletin* 1932, v 29 768].

The skin test for filariasis can thus only be used with safety when other species of nematodes are absent. This is a serious limitation of the test, because members of the Forces and others will be exposed to both filarial and intestinal species.

MAZZOTTI L. & OSORIO MARIA T. The Diagnosis of Enterobiasis. Comparative Study of the Graham and Hall Techniques in the Diagnosis of Enterobiasis. *J. Lab. & Clin. Med.* 1945 Dec. v 30 No. 12 1046-8.

“Examinations for the diagnosis of enterobiasis were carried out in 430 individuals using both the Hall and Graham techniques. The percentage of positive results obtained was 32 per cent. with the Graham method and 16 per cent. with the technique of Hall.”

DEFICIENCY DISEASES

CHURCHILL, M H Dietary Deficiency Diseases among Prisoners of War *J Roy Army Med Corps* 1945 Dec. v 85 No 6 294-8

This paper is based on notes of nearly 500 cases of deficiency disease occurring in prisoners of war in Singapore and Thailand during the period 1942-1945. Elaborate examination was often not possible and treatment was difficult owing to lack of supplies.

A type of amblyopia was a common condition the first cases appeared within 4 months of the prisoners going on to the Japanese ration scale. In rather less than half the sufferers there was an association with some better recognized symptom of deficiency. The outstanding symptom was blurring of vision but this was preceded by smarting of the eyes lachrymation and photophobia. The failure of sight was often progressive and severe in other cases it progressed to a certain stage and then remained stationary in others again it varied improving when there was any substantial improvement in the diet. Two factors seemed to be concerned in producing the condition dietary deficiency and intense sunlight. There was no apparent correlation between the defect in vision and the ophthalmoscopic appearances. About half those examined showed some degree of cupping or excavation of the disk.

Observations on pellagrous conditions on beriberi and on some other aspects of vitamin deficiency are recorded. No evidence was found of deficiency of vitamins A and C.

KRISHNAN B G RAMACHANDRAM S & SADHU K. The Treatment and Prevention of Vitamin-B₁ Deficiency in Infants a Public Health Experiment. *Indian Med Gaz* 1945 Oct. v 80 No 10 521-4

Infantile beriberi is far from uncommon in the Northern Circars of Madras Presidency and an inquiry centre was set up in Cocanada in 1942. This paper gives an account of its activities. The authors start by describing the disease which is vitamin B₁ (or thiamin) deficiency in infants of beriberi mothers and which differs in most respects from beriberi in adults. The symptoms may set in abruptly in an infant apparently in good health with cyanosis dyspnoea and tachycardia and may run a fulminating course ending fatally in a few hours. In others there is colic with fits of screaming vomiting diarrhoea and convulsions. Still more chronic cases occur which are characterized by pallor vomiting and signs of marasmus. Aphonia is a common symptom. Injection of vitamin B₁ brings about dramatic cures even in infants seemingly moribund.

At the Cocanada centre 1 145 infants had been treated by the end of 1945 all were breast fed and their ages ranged up to 12 months but most of the cases were in those under 6 months and the peak was at about 4 months. Of the total 980 (85.5 per cent.) were discharged as cured, but in 68 (6.9 per cent.) of these relapse or recurrence took place at intervals up to 3 months. Only 16 deaths occurred. Prophylaxis—giving one tablet of the vitamin (1 mgm) to the mother once each day during 3 months before and 6 months after delivery—was tried and of 54 so treated, who had previously lost babies 28 had infants which developed the disease in spite of the vitamin administration. Twelve others with a similar history but who were not given prophylactic vitamin tablets had 8 living children all of whom developed infantile beriberi and were cured. The dosage used 1 mgm. tablets administered regularly seemed to be of some value, but was probably inadequate for the women were living on a diet very deficient in vitamin B₁.

and hookworms was however not constant one third of the recruits with under 11 gm Hb had no infestation while one-third of those with moderately heavy infestations had over 14 gm Hb. It was concluded, therefore that hookworm infestation was a secondary factor in the production of the anaemia.

Over three-quarters of the total anaemia in all classes was normocytic (MCV between 80 and 100 μ) In both Madras and Punjab about 60 per cent. of the normocytic anaemia was normochromic (MCHC 30 per cent. or over) but in United Provinces recruits 90 per cent. was normochromic and only 10 per cent. hypochromic (MCHC less than 30 per cent.)

In both Madras and Punjab about 20 per cent. of the total anaemia was microcytic (MCV less than 80 μ) and about half the microcytic anaemias were normochromic. In United Provinces recruits only 2 of 39 cases of anaemia were microcytic and both these were normochromic.

Only five very mild cases of macrocytic anaemia (MCV of 100 μ . or over) were found. Two were from Madras two from United Provinces and one was from Sind. One of the Madras had a hypochromic macrocytic anaemia, and the remaining four were normochromic none had bilirubinaemia or splenomegaly. No case of macrocytic anaemia was found in the Punjabis.

In both Madras and Punjab about 45 per cent. of the anaemia was hypochromic, but in United Provinces recruits the proportion was only 10 per cent. The frequency of hypochromic anaemia was greater among the severe anaemias where the haemoglobin value was below 10 gm. 11 out of 13 cases were hypochromic. Extreme hypochromia (MCHC less than 28 per cent.) was rarely seen except in the more severe anaemias only three of fifteen such cases having over 11 gm Hb. Contrary to expectation hypochromia, a sign of iron deficiency was not more frequent in men infested with hookworms than in the non-infested.

Whereas 58 per cent. of recruits with haemoglobin levels over 14 gm. had a MCHC of 32 per cent. or over this value was exceeded in only 35 per cent. of the normochromic anaemias. This difference is statistically highly significant but while red cells with a MCHC below 30 per cent. are certainly unsaturated, those with a MCHC a little over 30 per cent. may be saturated or unsaturated.

The change to army life and diet in itself, considerably improved the anaemias of the recruits but a group given in addition 8 grains of ferrous sulphate daily improved very much more. On recruitment, both the group given iron and the untreated group contained about 45 per cent. of anaemic men and about 25 per cent. of men with haemoglobin levels of 14 gm. or over. After 3 months training 31 per cent. of those not receiving iron were still anaemic and 50 per cent. had 14 or more gm. Hb. whereas of those taking iron only 8 per cent. were anaemic and 80 per cent. had levels of 14 gm. or more. Two months later those taking iron had improved still further but no significant change had occurred in the others. The observations showed that in both groups men with initial haemoglobin levels of between 14 and 14.9 gm. were capable of improvement. All types of anaemia seemed to respond equally well. Hookworm infestation had no measurable influence on the haemoglobin regeneration in either group even when the infestation was moderately heavy. The responses of the Madras and Punjabis were very similar but in both groups the haemoglobin classes of United Provinces recruits were slightly inferior. The red cell count and packed cell volume both rose with the haemoglobin and were significantly higher from one month onwards in those taking iron than in those not taking it.

There were many puzzling features about this universal response to iron therapy. Only 4 per cent. of the men who benefited from iron had typical iron-deficiency anaemias and only 30 per cent. had any of the usual signs of iron deficiency. Furthermore, nutrition workers have deduced from analyses

that even the poorest Indian diets have an iron content adequate even for the greater needs of women. It is possible that a great part of the iron of the poor Indian diet is for some reason not assimilable. Apart from the original chemical form of the iron there is little knowledge of the influence on its absorption of mineral balance and such interfering substances as phytic acid. It is also possible that some dietary deficiency that may be the major cause of the anaemia prevents the utilization of iron and that when that factor is replaced iron is still necessary to build new haemoglobin. Finally it is possible that the benefit observed was due not to iron but to traces of some other metal present in the ferrous sulphate and deficient in the common Indian diet. Beyond speculation however it is clear that most recruits benefited from a daily dose of ferrous sulphate. The authors suggest that only when the haemoglobin level exceeds 15 gm should it be considered satisfactory—a standard reached by only 25 per cent of the newly joined recruits other than nursing sepoy.

MOORE C V, BIERBAUM Olga S, WELCH A. D & WRIGHT L. D. The Activity of Synthetic *Lactobacillus cases* Factor (Folic Acid) as an Antipernicious Anemia Substance. I. Observations on Four Patients. Two with Addisonian Pernicious Anemia, One with Nontropical Sprue and One with Pernicious Anemia of Pregnancy. *J Lab & Clin Med* 1943 Dec v 30 No. 12 1056-69 4 figs. [30 refs.]

Clinical and hematologic remissions were induced in two patients with Addisonian pernicious anemia by the daily oral administration for ten days of 30 mg and of 100 mg of synthetic *L. cases* factor (folic acid) respectively. One patient with macrocytic anemia of nontropical sprue and one patient with pernicious anemia of pregnancy responded in a similar manner when given daily 20 mg of the preparation intravenously.

Reasons are given for interpreting these results as indicating that *L. cases* factor possesses antipernicious anemia factor activity. It is pointed out however that the material must be proved effective parenterally in much smaller doses and over a much longer period of time before it can be accepted as being closely similar in action to (or identical with) the effective principle present in liver extracts.

DISCOMBE G. Criteria of Eosinophilia. *Lancet*. 1946, Feb 9 195-6 [12 refs.]

As it became necessary accurately to determine the eosinophil counts of a series of patients and as the limited staff was insufficient to undertake by ordinary methods the large number of differential counts required the possibility of using a simpler and more rapid technique for the determination of eosinophilia was considered.

Although cover-slip films are less subject to errors due to differential distribution of cells than are smears on slides mathematical calculations showed that increases in the proportion or absolute number of cells present to the extent of 1-5 per cent in blood can be detected with certainty by a differential count only if very large numbers of cells are counted in cover slip preparations. However methods for counting eosinophils in a haemocytometer have been devised and as the uncertainty of such counts varies with the square root of the number of cells counted the error can readily be made as small as desired by counting more cells. The following method was therefore adopted—

Blood is diluted with the fluid (1 per cent aqueous eosin) and acetone 5 volumes each distilled water to 100 volumes (this keeps for some weeks) and after mixing is allowed to stand for 5 minutes. After the pipette has been

shaken vigorously by hand for 2-3 minutes, a Fuchs-Rosenthal chamber is filled and when the cells have settled (1-2 minutes) the preparation is examined with a 2/3 in. objective and a $\times 10$ eyepiece under the most brilliant illumination tolerable. In such preparations the unstained leucocytes cannot be seen and the eosinophils stand out as deep red particles easily countable. clumping is unusual, but if it develops the preparation must be rejected. Careful investigations showed the method to be entirely satisfactory. For routine work, two pipettes should be filled, and one Fuchs-Rosenthal chamber filled from each. If the whole ruled area (3.2 sq. mm.) is counted and 104 or more eosinophils are found, corresponding to a count of 325 per cmm. it is certain that eosinophilia is present. The normal range of eosinophils is up to 240 per cmm., and not more than 1 per cent. of normal subjects should have counts above this.

It was possible to demonstrate a mild degree of eosinophilia (400-500 per cmm.) in most quiescent asthmatics but the method was principally used in following the treatment of patients with injections of gold salts as it has been shown that toxic manifestations of chrysotherapy are associated with eosinophilia, and as routine differential counts have been recommended for the early detection of this toxicity.

SIMONET P. & GIRARD J. Syndrome de Loeffler à forme macronodulaire chez une asthmatique [Loeffler's Syndrome in an Asthmatic.] *Semaine des Hôpitaux de Paris* 1948 Feb 21 & 22, No 7 288-90 4 figs.

VENOMS AND ANTIVENES.

ABUJA M. L. & BROOKS A. G. A Suggested First Aid Treatment for Cobra Bites with Carbolic Soap Solution. *Indian Med Gaz.* 1945 Sept., v 80 No. 9 461-3.

As long ago as 1924 the observation was made that soaps could detoxify snake venoms and CARMICHAEL [this *Bulletin* 1928 v 25 291 and CERARI & BOQUET (*ibid* 1938 v 35 435) showed that sodium ricinoleate was antitoxic *in vitro* to *Crotalus* and *Liaspis aspis* venoms.

The authors have tested the action of many substances—colloidal metals, dyes, biological products—to ascertain their detoxifying powers against cobra venom in pigeons but all were ineffectual. They then tried various soaps and obtained success with emulsions of Lifebuoy carbolic soap which is to be found in most homes. The soap in 5 per cent. emulsion, infiltrated in doses of 1-2.5 cc. at the site of inoculation of the venom into pigeons of about 300 gm. weight, is effectual against 0.4 mgm. of venom when injected even as late as 1½ hours afterwards. Fourteen survived out of 18 whereas all of 10 untreated died. Even in those which did not survive death was delayed for several hours. This delay would in many cases enable antivenene to be obtained and, in the authors' experiments where the soap was followed by antivenene even as long as two hours later many survived larger doses still of the venom.

The authors give details of the method which they recommend. If a finger is bitten a tourniquet is applied at the base of the finger and another above the elbow. If a toe at the base of the toe and above the knee then the 5 per cent. soap emulsion (which could be kept ready at the local dispensary with a sterile syringe) should be injected, 0.5-1.0 cc. at points surrounding the bite—5 cc. in all could be given—and bleeding encouraged by crucial incisions with a razor blade. Potassium permanganate they regard as valueless and even harmful.

as it may cause sloughing and gangrene. The soap must not be given intravenously and never as a substitute for antivenene. It is purely a *first-aid treatment*.

The authors ask that it may be tried more widely and invite reports especially regarding the following points for information —

- (a) Was the snake definitely identified as a cobra?
- (b) Site and details of bite
- (c) Interval elapsing between bite and injection of soap solution
- (d) Quantity of soap solution injected.
- (e) Antivenene (including period after bite at which serum was given dosage and whether administration was intravenous)
- (f) Other details with regard to local reaction symptoms and progress of the case

H Harold Scott

DERMATOLOGY AND FUNGUS DISEASES

EPSTEIN E. The Lichen Planus—Eczematoid Dermatitis Complex of the Southwest Pacific. A Study of 65 Cases. *Bull U.S Army Med Dept* 1945 Dec v 4 No 6 687-94

In an introductory paragraph to this paper Epstein records that when it was written the dermatoses contracted overseas were assuming a major aspect in the disabilities suffered by the armed forces and that those serving in a medical unit which received evacuees from all battle fronts developed a healthy respect for the skin injuring factors in the Southwest Pacific particularly in New Guinea and the adjacent islands. The malady which he names the lichen planus—eczematoid dermatitis complex (known to the troops as jungle rot) was the most frequent cause of evacuation for skin diseases from this area. Of a series of 65 cases exhibiting the malady 34 per cent. were in the 25 to 29 age group and 35 per cent. were older than 35 years of age. The sex incidence was approximately equal race did not seem to be important brunettes were more commonly affected than blondes. Usually the patients had spent three to six months in New Guinea before developing an eruption. The first lesion frequently appeared on an exposed area. Occasionally a generalized oedematous desquamative dermatitis developed in a few days but in most cases from one to three months were required for full efflorescence. The lesions were of three types two of which co-existed in more than half the patients. The first type was an aberrant variety of hypertrophic lichen planus the lesions being purplish, coalescent nodules having smooth scaly warty or pseudo-desquamative surfaces. The face palms and soles were frequently affected. The eruption which might be either localized or generalized did not tend to follow the usual distribution pattern of lichen planus. Sometimes marked atrophy or pseudoatrophy followed the disappearance of the primary lesions. The details in which despite its general appearance the eruption differed from true lichen planus were atypical localization occasional atrophic sequelae abnormal histological features absence of typical lichen planus papules marked pigmentation and frequent transformation into an eczematoid exfoliative dermatitis-like eruption. In the second form the eruption was eczematoid and affected especially the legs hands forearms neck and ears the lesions erythematous-violaceous in colour were flat and covered with branny scales. The underlying skin was often thickened. In the more acute varieties the lesions oozed. The nails showed changes such as those which occur in eczematoid eruptions of the extremities. Sometimes generalized exfoliative dermatitis supervened. The third variety

that the rate of sickness declined. Of 1,500 men, 15 died in 7 months a proportion which compared favourably with the monthly death roll of 60-120 in neighbouring camps. Local purchase of food (rice-polishings and meat) and drugs was allowed—prices were very high.

At this time the main diseases were malaria, beriberi, tropical ulcer and dysentery (amoebic increasing and bacillary decreasing). Shortage of specific drugs presented a difficult problem when it came to deciding to whom they were to be given. Diphtheria occurred but in spite of the fact that no anti-toxin could be obtained there were only two deaths in 20 cases—in some of these cases Vincent's infection was probably also present.

Later the Japanese abolished the weekly half-day rest and the men were given no chance to wash or air their clothes. Scabies ringworm and other skin affections were rife—the huts were heavily infested with bugs and lice scrub typhus, beriberi pellagra, malaria, the dysenteries and tropical ulcers were becoming increasingly common. The Japanese, however began to issue pay to the prisoners who all subscribed to a central pool for purchase of supplementary food and drugs—rice-polishings were bought and issued each day with the result that there was a marked decrease in the incidence of beriberi.

Later the battalion moved into an area in which cholera was prevalent but the men (who were mostly educated) had previously been warned by the author and instructed how best to prevent infection, with the result that only seven died whereas other units lost up to 50 per cent of their strength. The Japanese commander—a non-commissioned officer—refused to permit the organization of a sanitary squad big enough to cope with the situation or to allow water to be drawn from the river above the point at which the coolie labour force contaminated it. The coolies themselves were badly affected by the epidemic and large numbers died—they were allowed no medical attention, and were given neither food nor water except that which the British orderlies surreptitiously passed to them. The dead were buried in pits necessarily dug much too close to the camp because there were not enough men to clear the jungle. [In many other camps the dead were cremated.] The author had already constructed a small plant for the distillation of water for intravenous salines and this form of treatment was used during the outbreak together with the oral administration of potassium permanganate (3 grains every quarter of an hour). In a few cases sulphapyridine was used apparently with good results.

It was not surprising that after months of these appalling conditions, with more or less constant incapacitation from one or several of the prevalent diseases and totally inadequate facilities for treatment the more chronically sick tended to become apathetic and exhausted beyond endurance. [Persuading these men to eat was a continual difficulty.]

GHOSE, L. M. & PANDA, D. A Case of Rhinoscleroma. *Indian Med Gaz.* 1945 Oct. v 80 No 10 511 4 figs. on 1 pl.

HARVEY, A. M., KUFFLER, S. W. & TREDWAY, J. B. Peripheral Neuritis. Clinical and Physiological Observations on a Series of Twenty Cases of Unknown Etiology. *Bull Johns Hopkins Hosp.* 1945 Aug. v 77 No 2, 83-103 5 figs. [13 refs.]

The condition described in this paper occurred among men of the United States forces who had served in the tropics. In 16 of the patients the common peroneal nerve was involved, in three the axillary and in one the radial. No known aetiological factor to account for the neuritis could be discovered, and there was no evidence of diphtheria or of vitamin deficiency. In the majority of the patients the condition appeared suddenly the onset being gradual in

only four of the series. In eight of the patients there had been an attack of benign tertian malaria within eight days of the onset of the neuritis two had had malaria at some other time but in the remaining ten patients there was no clinical or laboratory evidence of malaria.

In all cases the patient's complaint was of weakness of an extremity. The three men with axillary nerve involvement and two of the others complained of severe pain. Numbness or paraesthesiae occurred in 14 of the patients. Loss of muscular power was most marked in the patients with axillary nerve lesions all these had complete loss of deltoid function and in two of the three there was evidence of involvement of other nerves of the brachial plexus. Muscular weakness was not so prominent a feature in the patients with peroneal nerve involvement in only three of these was there much atrophy. Laboratory investigations did not help in clarifying the aetiology of the condition.

Electromyographic studies were made on the affected muscles by stimulating the nerve trunk with condenser discharges or an induction coil and recording the action potential in the muscles by cathode ray oscillograph. It was found by this method that the voltage of the action potential of the affected muscles was less than normal. The amount of reduction of voltage was proportional to the muscular weakness as assessed clinically. When a second stimulus was induced at a short interval after the first the affected muscle responded in a manner similar to a normal muscle. There was no evidence of a summation of impulses at the neuromuscular junction. It was thought these facts indicated that the nerve fibres which were affected were completely inactive surviving fibres functioning normally and that there was no defect of muscle fibres. A tetanic stimulation did not produce a myasthenic response nor did prostigmine alter the character of the muscular contraction.

Treatment consisted in rest the prevention of stretching of the affected muscles and graduated exercise. The radial palsy and with one exception the peroneal palsies all improved slowly to satisfactory recovery but the axillary palsies did not recover while under observation. The authors concluded that the neuritis could not be connected with the antimalarial suppressive treatment with quinine and atabrine which all the patients had had. Nor was there any evidence in favour of a vitamin deficiency.

The possible relationship between the condition described and malaria is discussed. The type of neuritis which the authors found in association with malaria presented as polyneuritis with pain and heightened muscle tone whereas the patients in this series complained of weakness in muscles supplied by a single or a few nerves. Pain was not consistent and muscle tone was poor. It is concluded that malaria was not primarily responsible but might have been a precipitating factor. The literature is reviewed and attention is drawn to the reports of similar cases made by SPILLANE and by WYBURN MASON. The paper ends with the case histories of two patients who presented typical signs and symptoms.

[This is yet another report on a series of cases of a type of neuritis which is receiving increasingly more attention in the medical press. One would have welcomed information as to whether any of the patients had received prophylactic or therapeutic serum injections.]

W. Tegner

VAN DEN BERGHE L. Syndrome thrombopénique ou onyali. Observation d'un cas provenant du Congo Belge. [Thrombocytopenia, or Onyali, in a Patient in the Belgian Congo.] *Ann Soc Belge de Méd Trop* 1945 June 30 v 25 Nos 1/2 49-55

The importance of this case lies in the facts that the patient was a European and that his history of symptoms prior to those characteristic of onyali were

peculiar. After a journey of three months in the bush the patient in September 1938 complained of feeling tired and consulted a doctor who could find nothing definite. The man therefore continued on his way. Soon afterwards he felt severe pain in the left wrist which became swollen and the following day the right wrist swelled in the same manner. After the application of hot compresses for three days these symptoms disappeared. The right shoulder was then affected but cleared up on similar treatment after a week. Eight days later the left knee swelled and was so painful as to prevent sleep but he continued at work and the condition cleared up in eight days. Some time later he felt discomfort in the teeth and small bullae appeared at the base of the lower incisors. He noticed that he was becoming jaundiced. In January 1939 he complained of dryness of the throat and difficulty in swallowing followed by an acute pharyngitis with marked swelling and for four days he could swallow nothing. Gargles and inhalations gave relief but haemorrhage from the mouth and gums supervened and the jaundice increased. While being examined by the doctor he had a fainting attack followed by coughing or vomiting of blood [it was not decided which]. Thereafter he had frequent bleedings from his gums and spat up blood. Slight exertion caused much shortness of breath. He went into hospital towards the end of February and a blood examination yielded the following information: red cells 800 000 leucocytes 3 600 thrombocytes 5 600 per cmm. haemoglobin 27 per cent colour index 1.6 erythroblasts numerous. He was seen by a specialist cardiologist who prescribed salicylates which made him worse. Red cells fell to 600 000 white 2 000 per cmm., haemoglobin 15 per cent. He was then given blood transfusions without much improvement till some 20 had been given when the red cells reached 4 million. More transfusions of 250 cc. were given on alternate days and the red corpuscles rose to 4 700 000 the white cells to 4 600 per cmm. and the haemoglobin to 99 per cent. Thrombocytes now were 80 000. He was kept under observation and was seen every three months for four years and remained well. In 1944 he was killed fighting in the great war.

The causation is considered but no conclusion is arrived at. It is suggested that insect bites might have injected some hypothetical virus or that as on his journeys he often had to push his motorcycle for considerable distances his head would then be near the petrol tank and he may have been poisoned by inhalation of petrol fumes.

SMOURIE K. L. An Outbreak of Lathyrism in Central India. *Indian J Med Res* 1945 Oct. v 33 No 2 239-47 [15 refs.]

The outbreak studied by the author occurred in the eastern part of Bhopal State Central India. At least 1,200 are said to have been attacked. He examined some 150 and studied more closely about half that number. Most of these were in the second and third decades of life and males preponderated over females in a proportion of 7 or 8 to one. Of 69 cases specially noted 56 occurred during the three months August-October the figures being 11, 23 and 22, respectively. There is nothing particular regarding the symptoms: they were typical. Those attacked were of the poorer classes. For the past 2-3 years the crops have been bad and damaged by rust, blight, bad weather etc. and the people have mixed cheaper grains in increasing amounts with the wheat, and for some months—six or more—had been consuming large quantities of *Lathyrus sativus*. Examination did not discover any admixture with *Vicia sativa*.

Lathyrus can be consumed in small or even moderate quantity with impunity but when it has to be used almost exclusively for six months or so danger is imminent. The obvious remedies are to provide alternative crops and improve

the condition status and earning power of the agricultural labourer. In the words of the author prevention is a social economic administrative and agricultural problem. *H Harold Scott*

MIRSKY C. A Case of Stinkblaar (*Datura stramonium* L.) Poisoning associated with Hyperpyrexia. *Clin Proc Cape Town* 1945 Nov v 4 No. 9 509-12.

FRACHTMAN H J & MCCOLLUM W T Portuguese Man-of-War Stings Case Report. *Amer J Trop Med* 1945 Nov v 25 No 6 499-500

A sailor aged 23 when swimming was stung on his arms and thighs by a Portuguese man-of-war (the jelly fish *Physalia pelagica*). An hour and a half later he was nauseated and soon afterwards began to have spasms of the abdominal muscles. His temperature on admission to hospital was only 98.6°F but the pulse was 96 and respirations 24 per minute and he was very apprehensive. Little or nothing abnormal was discovered by blood examination red corpuscles were 4½ million leucocytes 11 500 per cmm haemoglobin 14.9 gm and the differential leucocyte count normal. Red lines not raised were visible over the front of the right thigh and shoulder. In spite of the spasms of the abdominal muscles and diaphragm there was little if any respiratory distress but the muscular contractures became more severe and spread to the neck arms and legs with muscular pain. External stimuli such as bright lights jarring of the bed or sudden noises precipitated the attacks the mind remained clear. Ten hours later respiration was slow and laboured, interrupted by diaphragmatic spasms but there was no cyanosis and the temperature pulse and blood pressure were within normal limits [our italics]. On the next two days the patient was better in the mornings but the symptoms returned later in the day during the next five days the spasms gradually diminished and on the sixth had ceased altogether and recovery was complete and uninterrupted. [The patient was said to be a well-adjusted individual who had no abnormal psychoneurotic tendencies but he was very apprehensive and the fact of respiratory distress without cyanosis or change in pulse rate is much in favour of a hysterical element being present. Nothing is said of the pain and numbness which are usually present in stings by *Physalia* but a choking sensation dysphagia and dyspnoea are common together with spasm of the abdominal muscles. This case is perhaps peculiar in the prominence of the last named symptom.] *H Harold Scott*

GENERAL ENTOMOLOGY

KNIPLING E F The Development and Use of DDT for the Control of Mosquitoes. *J National Malaria Soc* Tallahassee Fla. 1945 June v 4 No 2 77-92. [23 refs]

At the laboratory of the Bureau of Entomology and Plant Quarantine in Florida U.S.A. investigations into the uses of DDT for mosquito control began in October 1942. In this paper the author briefly summarizes and in some cases discusses a number of the tests made in the laboratory and in the field against larvae and adults of the following anophelines and culicines *Anopheles quadrimaculatus* *Anopheles albimanus* *Anopheles crucians* *Culex quinquefasciatus* [*C fatigans*] *Aedes aegypti* and *Aedes taeniorhynchus* (234)

wise in the marrow the sharp edge cuts the marrow so that the groove is filled. A cannula fits over the rod in its upper part between the proximal end of the groove and the handle.

The point is made to enter the bone vertically then the handle is depressed to an angle of 30° to the surface of the sternum and the rod is pushed into the marrow for 1 cm. It is then rotated clockwise for one or two turns and withdrawn the cannula preventing the soft tissues from displacing the marrow from the groove. Satisfactory smears can be made, the cell counts being more accurate than in smears of marrow obtained by aspiration where dilution with blood occurs [see also MERTENS this *Bulletin* 1946 v 43 257]

J. F. Corson

SUÁREZ R. M. DÍAZ RIVERA R. S. & HERNÁNDEZ MORALES F. Hematological Studies in Normal Rhesus Monkeys (*Macaca mulatta*). 1. Venous Blood Studies. 2. Bone Marrow Studies. *Puerto Rico J. Pub. Health & Trop. Med.* 1942, Dec. v 18 No 2, 212-23 1 pl. [Refs. in footnotes.] [Spanish version 227-41.]

Being struck by the scarcity of publications dealing with the cell content of normal monkey blood and the complete lack of information regarding the cells of the bone marrow the authors decided to study the blood and bone marrow in normal rhesus monkeys of various ages. The blood was obtained from a peripheral vein in 38 while the bone-marrow was aspirated from the sternum of 40. The general results of the study of this material are given in the summary to the paper which is as follows:—

"1 Hemoglobin estimations for 38 Rhesus monkeys were as follows: infant monkeys 84.62 per cent. young 90.5 per cent. adult, 91.16 per cent., with ranges of 76 to 94 80 to 110 and 76 to 117 per cent. respectively.

"2. Red blood cell count averaged 4,197,500 in the infant 5,172,500 in the young, and 5,235,000 in the adult animal.

"3 Platelet count averaged over 300,000.

"4 Reticulocyte counts were 2.9 per cent. for infant, 1.85 per cent. for young and 1.58 per cent. for the adult animals.

"5 The average total leukocyte count was 15,107 for infant 17,562 for young and 9,999 for the adult animals.

"6 Metamyelocytes averaged 0.75 per cent. in the infant, 0.5 in the young and 1.15 in the adult animals.

"7 Neutrophils were more abundant in the venous blood of the adult than in that of the young or infant monkeys the average for the infant being 36.12 per cent., for the young, 39 per cent. and for the adult 50.25 per cent.

"8. Eosinophilia was quite pronounced in the young and adult monkeys which may be attributed to intestinal parasitism. Averages of 3.06 were found for infant animals 4 per cent. for young and 4.92 for adult.

"9 Lymphocytes were found in higher percentages in both infant and young animals than in adult, such percentages being above 40 in all the series analyzed. Averages were given of 57.75 for the infant, 58.75 for the young, and 42.19 for the adult animals.

"10 It was the authors impression that there is a relative proportion of different blood elements in the monkey comparable to those of the human infant and young however these differed slightly from the venous blood of the adult human.

"11 Morphologically the neutrophils and eosinophils appeared to have multiple lobulations in their nuclei sometimes as many as thirteen to fourteen lobes were counted in one cell. The lymphocytes appeared to be larger than in human blood and, in many cases coarsely granulated.

The following results were obtained among the forty *Macacus* submitted to bone marrow aspirations

1 The average erythrocytic series in the infant was higher than in either the young or the adult animal

2 The average granulocytic series was higher in the adult than in either the infant or young the young animal's marrow being richer in those cells than the infant's

3 The young monkey had more erythrocytic cells in its marrow than the adult.

4 Lymphocytes were more numerous in the infant and the young than in the adult monkey

5 Ratios for erythrocytic and granulocytic components were as follows
infant 1.28 young 1.3 adult 1.4

6 Morphologically the cells of the bone marrow resembled those of humans except for the multiple lobulations of the nuclei of the polymorphonuclear leukocytes and for the larger size of the lymphocytes of the animal.

7 Megakaryocytes were seen in very low percentages 0.2 in only two adult animals. None were seen in either young or infant monkeys

8 If it were not for the high number of lymphocytes the bone marrow of the monkey would approach the human picture at different life stages.

C M WENYON

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

WENYON C. M. *Tropical Medicine in War and Peace. Trans Roy Soc Trop Med & Hyg* 1945 Dec. v. 39 No 3 178-94

This presidential address refers to the stimulus provided by the two world wars to research into the possibilities of improving methods of safeguarding the health of troops in tropical and sub-tropical countries. Very noteworthy contributions to tropical medicine were made in both. During the 1914-18 war LEIFER worked out the life-history of *Schistosoma haematobium* and *S. mansoni*. Important additions to our knowledge of the dysenteries were made. Weil's disease was intensively studied. The louse was incriminated as the vector of European typhus fever and the Weil-Felix reaction was elaborated. The limitations of quinine in the treatment of malaria were more clearly defined as a result of war experience.

The second world war has been even more productive of new knowledge than the first. Most important of all perhaps is the knowledge of what atabrin can do to prevent clinical malaria among troops operating in hyperendemic malaria country. The important work of FAIRLEY and his colleagues at Cairns in Australia is strongly suggestive of the existence of an exoerythrocytic cycle of development of the human malaria parasite. The discovery of the remarkable insecticidal properties of DDT is of great and far-reaching importance. Insect repellents have been discovered—dimethyl diethyl, and dibutyl phthalates—which do what is claimed for them. A vaccine against scrub-typhus (tsutsugamushi disease) has been prepared and used, but the results have not yet been reported. Against louse-borne typhus a formalinized rickettsia vaccine prepared from egg yolk cultures has been widely used and it is believed that some degree of protection was afforded, but DDT has given the most remarkable results in the prevention of typhus fever. A shirt impregnated with DDT retains its insecticidal properties throughout a number of launderings. In the treatment of bacillary dysentery sulphaguanidine has

been used with most satisfactory results and it is possible that other sulphonamides may be even more effective. In amoebic dysentery cases that are resistant to anti-amoebic remedies marked clinical improvement may follow the administration of penicillin but without eliminating amoebae after this improvement the amoebic infection may become amenable to specific treatment. The war years also saw the final proof that kala azar in India is transmitted by *Phlebotomus argentipes*. Russian investigations in Middle Asia showed that a gerbil, *Rhombomys opimus* is the reservoir of the leishmania of oriental sore which is transmitted to man by *Phlebotomus papatasi* another sandfly *P. caucasicus* being responsible for maintaining the rodent infection in the burrows. Such are the outstanding achievements of tropical medicine during these last war years.

The address then dealt with the future of tropical medicine and with the present state of tropical medicine in Great Britain. At present the facilities for giving instruction in tropical medicine in London, as well as for the study of tropical diseases and their treatment are sadly deficient. A very strong case is made out for the early creation in London the centre of an Empire with vast tropical responsibilities of a Tropical Medicine Centre which would combine a hospital for tropical diseases and a school of tropical medicine. This "would restore the position formerly held by this country would be a monument to the many pioneers who devoted themselves to the study of tropical disease and would be a centre of tropical medical activity worthy of the British Empire."

1. In the introduction to this series of papers Allan remarks that there is now much more movement into and out of the Native Territories of South Africa than was the case 25 years ago and that this movement has entailed much spread of disease and much change in mode of life. During the last 4 years a concerted attempt has been made to deal with these diseases, and the work will be continued.

ii. The paper by Mears is largely concerned with the official duties and private practice of the District Surgeons. He discusses certain grievances but from the point of view of readers of this *Bulletin* the important part of the paper is that in which it is stated that in the Transkei there are 1,281,823

Africans 17,598 Europeans and 10 000 Coloured for this population there are 13 hospitals (8 of which are mission hospitals) with 607 beds and about 50 doctors

iii. De Villiers refers to the basic reasons for the deterioration of agriculture and health in the Transkei which for many years has been a matter for concern. The land has become seriously eroded and denuded as a result of over stocking and inefficient farming there has been a steady deterioration in the quality of cattle and a shortage of milk for human consumption. The result has been serious malnutrition and heavy infant mortality. [The general position was set out in the series of papers reviewed in this *Bulletin* 1943 v 40 865] Plans have now been made and work started to improve the general agricultural position. The project is very big but not too big for the problem it entails much engineering construction work afforestation agricultural supervision and education and introduction of new stock with restriction of the old. It is a programme which will affect health chiefly because it is directed against the fundamental causes of ill-health malnutrition and ignorance. Already a useful amount of work has been done.

iv. Hubbard takes up the subject of afforestation and fuel supply showing that at present the wood taken for fuel is much below even a reasonable minimum yet because this wood is scarce the people burn farm manure and mealie stalks which are needed to fertilize the land. Moreover timber is an essential for construction purposes in any health or industrial programme. The proper degree of afforestation is therefore important for health and the balance between the use of land for this purpose and for agriculture must be worked out with care.

v. Drewe discusses leprosy as he has seen it at the Holy Cross Mission Hospital. Many of his points have already been noticed in this *Bulletin* 1945 v 42 292.

vi. The paper by Fraser Shearer is well described by its title those who have practised surgery in Africa will recall cases similar to those he describes of the immense resistance to shock and infection exhibited by the Africans. He makes one point of public health importance, however in his remarks on the senile patient with chronic pulmonary tuberculosis and positive sputum who lives with his family during his slow decline and infects the younger members. If we trouble to elicit his family history we find in 80 per cent of cases that the patient's children and even grandchildren have died in numbers in their early teens of acute miliary tuberculosis. The building of hospitals for the acute cases in contacts seems futile while the source of infection is allowed to remain at home and to continue to infect others. The author suggests some form of segregation on farm colony lines for these chronic cases.

vii. The author of this paper Mr J H Dugard is an Inspector of Schools but he writes with authority for the administration of school feeding has been delegated to the Education Department. He points out that there is an obvious correlation between low income and malnutrition but also that ignorance of dietary factors often produces malnutrition even when the income is satisfactory. In most families in the Transkei the schoolchildren receive only one meal each day—on their return from school—and such children are suffering from starvation not mere malnutrition. It is to provide such children with enough food to prevent starvation that school meals are arranged. The author remarks that in the interest of national welfare collective action to prevent human deterioration is necessary by means of a well-designed feeding scheme for children. [National welfare is of course important but it would fit in with the ideals of medical men if equal stress were laid on the fact that starvation or any other adverse condition must be prevented in the interest of the child as an individual who is not responsible for his own environment]

and who should not therefore be penalized for it.] School-feeding is still in the experimental stage in South Africa, and the composition of the meals is not always good. The allowance of 2d. per meal is not ungenerous and at that price the diet designed by Dr S. KARK at Polela is good, but there is in some places too great a tendency to supply bread and jam, condensed milk, pork of dubious quality and mealie-meal with monotonous regularity instead of making determined attempts to procure protective foods. School meals should be regarded as breakfasts and should be given as early in the day as possible.

viii. The training to which the author refers consists of one year during which time women of approved capacity are given instruction in domestic, agricultural and medical subjects before they go to work among the African communities.

ix. In a table of facts about the Transkei it is stated, among other things that between 80 000 and 100,000 Natives leave the Transkei each year to seek work on the mines or in other industrial centres. 28 per cent. of families have neither cattle nor land. Smallpox was prevalent during 1945 but typhus was less in evidence than during 1944 perhaps because the outbreak of that year left a residual immunity. Approximately 100-200 persons with tuberculosis are repatriated from the mines each year.

x. This short note contains the outline of a most excellent plan by which students from the Medical Schools of the Union are given the opportunity of seeing for themselves the work carried out in the Native territories. They are introduced to the relationship of the soil to medical practice, of the place of afforestation in the health and welfare of the people, of the relative value of pamphlets and posters and the cinema in the education of the public, and why people leave the land to seek employment in overcrowded industrial areas.

xi. Miss Elder, the head of the Jeanes Teachers Training School All Saints Mission, gives a short account of the function and training of these African teachers in which she refers to the Jeanes School at Kabete in Kenya. Their name derives from Miss Jeanes, a Quaker lady of the United States, who founded the movement in the interest of better education for the Negroes. The object of these teachers is to widen the scope of school education to include training in practical domestic science, market gardening and small farming with instruction in hygiene, elementary nursing and cooking. The evidence all points to the need for such teaching among the Africans, and to the success of the efforts so far made, but she adds — It seems the greatest pity that the training of these teachers has now come to an end in the Cape Province and has never been started anywhere else in the Union for now is the time when a steady stream of such people joining the flood of workers that will be needed to rehabilitate the Transkei in the critical years to come might make a most valuable contribution to their country's welfare. A reader is left to wonder why the training of Jeanes teachers has been abandoned.

[This series of papers is important in that it gives the reader a picture of life at almost its lowest level in the people of South Africa, and in that it shows the field from which the impetus for improvement should arise. Medical men and social workers see as clearly as any others the ultimate effects of policies adopted by central governments and it is part of their duty to make the necessary representations to governments so that these policies can be modified where change is needed. The papers also demonstrate the obvious fact that good health depends upon agriculture and education no less than on strictly medical activities. These facts are appreciated by the Government of South Africa, and if the recommendations made in the *Report of the National Health Services Commission* (U.G. No. 30-1944) are put into effect there is every reason to believe that the situation will be radically altered for the better.]

This Commission set out comprehensive schemes for personal health services (promotive preventive curative and rehabilitative) and non personal health services with the object of applying them to all sections of the population according to their need and without regard to race colour means or station in life. No brief account of this long report is possible it is an admirable document which would serve as a basis for any scheme for comprehensive medical service in Africa and it should be studied in detail. The authors recognize the importance of agriculture to health but think that the function of a national health service in this respect is to advise but not itself to embark upon the provision of food. The report states that the long term policy with regard to nutrition is obviously to improve purchasing power. Consideration of this however would lead to a very complicated discussion of socio-economic problems beyond our terms of reference. The short term policy essential on health grounds should be to extend the activities already in operation especially in respect of protective foods and to subsidize consumption by low income groups particularly expectant mothers and pre-school children within these groups. An account of the substance of this report is given by A. R. PATERSON in the *East African Medical Journal* 1945 July v 22 No 7 204.]

ORENEY, Jean M. *The Health of Indian Women and Children.* *J. Ass. Med. Women in India* 1944 Feb. v 32 No 1 5-16

The author who is exceptionally well qualified to deal with the subject shows that the standards of health of Indian women and children are even lower than those of the population as a whole.

A few figures will suffice to illustrate the distressing wastage of life and health that still occurs. Corresponding figures for females in England and Wales are shown in brackets.

The expectation of life for Indian females in 1930 was 26.58 years (62-67 in 1931). The specific death rate for females in British India in 1930-32 at the ages 15-19 was 10.6 (2.3) and at the ages 20-29 it was 11.9 (2.9).

The maternal mortality rate for India is not accurately known it is estimated as 15-20 (2.76 in 1941). The wastage of life is most pronounced in early life of all the deaths occurring in British India the percentage among children under ten years is 48.5 (10).

The causes of the low level of health of women and children are discussed under the heading of social security education and organized public health. Details are given to show how utterly inadequate is the supply of medical women and health workers and a plea is made for the extended use of instruction in hygiene among teachers and schoolchildren.

A brief reference is made to the population problem it is stated that "A continuous adjustment between the population and the resources available will be needed and constructive thought must be given to the means of making these adjustments but no suggestion is made for the inclusion of the subject in the sphere of action of the public health department."

In a nutritional survey in an urban area at least 38 per cent. of the mothers were found to be malnourished and in a group of 284 infants 168 under the age of six months were in a good state of nutrition but when they had reached the age of one year only 31 could be placed in this category

GUNX D. L. KIRK, R. L. & WATERHOUSE, J. A. H. An Improved Radiation Integrator for Biological Use. *J. Exper. Biol.* 1945 Dec., v 22 Nos. 1/2, 1-7 3 figs. [10 refs.]

The authors describe laboratory work with radiation integrators which are instruments designed to sum up the amount of radiant heat received over a period.

A good many years ago Buxton was engaged on the study of climate in relation to insects. It was well known that radiation of many wave lengths is of very great biological importance but difficult to measure by any existing apparatus. He endeavoured to produce a relatively simple instrument and was prepared to be content with a relative figure even if it had been impossible to reduce the readings to some such units as gram-calories per unit of area and time. He produced an instrument which consisted essentially of a black bulb in vacuum full of a volatile liquid and exposed to the sun it was connected to a burette which was at shade temperature. Radiant heat from the sun falling on the black bulb heated it and caused the liquid to distil from the bulb into the burette. With this instrument he showed that there were large seasonal differences in the amount of radiant heat received at different seasons in the Samoan islands these differences were not shown by shade temperature owing to the thermostatic effect of the surrounding ocean.

The present authors have had the use of Buxton's original apparatus and have evolved improved types which can be made in a more nearly standardized manner. They have calibrated these instruments in the laboratory with a source of radiant heat and a pyrheliometer and they have developed the theory and made some approach towards obtaining absolute measurements.

An apparatus of this type has the advantage that one can control its sensitivity by altering the volatile liquid. The present authors find that if the instrument is exhausted and filled with water the amount of distillate is relatively small, so that the instrument can be read once a day to give a mean daily intensity of sunshine. If it is filled with alcohol, which is much more volatile it will give a measure of differences of intensity over much shorter periods.

It seems evident that radiant heat is an important and neglected element of climate. And it seems that this instrument is a simple one which could be set up and used in almost any meteorological station. We look forward to hearing results from tropical Africa, which these authors will shortly be publishing.

P. A. Buxton

BOOK REVIEWS

MONTEL, M. L. R. *Memento thérapeutique du praticien colonial*. [A Tropical Practitioner's Guide to Treatment.] 118 pp 1945 Paris Maasson et Cie Editeurs 120 Boulevard Saint-Germain. [100 fr]

The author of this book has had nearly 40 years experience of practice in the tropics and he holds the position of Medical Officer in charge of the Saigon Polyclinic where more than a thousand patients daily present themselves for treatment. Therefore as Professor Brumpt says in his prefatory note one is better qualified to write a work on colonial medical practice. The author claims that this work is a concise précis of therapeutics for colonial practitioners. He has intentionally omitted all history and discussion of the mode of action of medicaments and has made choice of such drugs only as he has found efficacious omitting also all references to the literature. In his introduction he states The colonial practitioner finds himself nearly every day confronted with emergencies and his intervention must be active energetic and prompt he ends by saying that this work is a résumé as complete as possible of the colonial practitioner's therapeutic armamentarium. These are very definite claims and it is only right that we should test them and see how far they are made good for a pocket manual if it is to serve its purpose of an aid in emergency must be accurate and precise in its information and is none the worse for being to a certain degree dogmatic.

It is to be feared that those who expect all this will be disappointed. There is much that is good but often the information which will be looked for is too vague to be of any help in emergency. Let us mention the good points first. The information is precise and helpful on the following subjects dysentery both amoebic and bacillary (though not many British practitioners will endorse the opinion that three pastilles a day of dysentery vaccine *per os* for three days are of much benefit in bacillary dysentery) ankylostomiasis schistosomiasis kala azar leprosy (though it is news to the reviewer that enuresis in infants should make one suspect leprosy) opium poisoning malaria (an excellent summary) sprue (but undue stress is laid on the action or failure of action of the pancreas) tetanus tinea imbricata and African trypanosomiasis.

Next to justify our statement that the information is often too vague to be helpful we may cite the following *Actinomycosis*. Sulphonamides dapsone thiazamide as adjuvant to the classical treatment. One is then referred to Blastomycosis and finds iodine internally and externally auto- and hetero-vaccines by injection by ingestion on dressings brewer's yeast penicillin. A mere list such as this without a word as regards dosage is not of much service. Agam under Yaws I use bivalent muthanol and quinby alone or together with sulpharsenol, acetylarsan and stovarsol nothing as to dosage or mode of administration. Under *Strongyloidosis* again merely a list thymol ethereal extract of *Filix mas* chenopodium may be tried and quinaquine stannoxyl, gentian violet methylene blue by mouth or intravenously arsenobenzene intravenously and antimonials. Many more examples of this vagueness might be cited but these will suffice.

Insolation is very poor nothing is said of the various forms of heat trauma and their different treatments. *Xerophthalmia* is dealt with in three lines under the complications of malaria. The author mentions that in *dengue* there occurs a swelling of the kidneys to such a degree that it is perceptible by renal ballotement and may even lead to the possibility of operation being undertaken for renal tumour. *Rabies* is not referred to at all. There are a number of misprints among them D D T and D T T are used impartially. The subjects are dealt with in alphabetical order so there is no pressing need for an index but it will be gathered from what has been said that the work is

difficult to place and, in spite of its good points the defects are such that in its present condition it cannot be unreservedly recommended as meeting the needs of the tropical practitioner

A Treatise on Hygiene and Public Health with special reference to the Tropics.
 Eleventh Edition pp xvi+707 181 figs. 1945 Calcutta Scientific
 Publishing Co. [Rs. 12/8 or 21s.] [Review appears also in *Bulletin of Hygiene*]

Thus the eleventh edition of Ghosh's *Treatise on Hygiene and Public Health* appears in less than two years after its predecessor—an interval shorter than that between any two previous editions. We do not know of course the size of the editions but the fact alone bears witness to the popularity of the work. Its merits have been repeatedly extolled in reviews of earlier editions in this *Bulletin* so there is little to add now. The issue of eleven editions in less than 33 years is recommendation enough of its usefulness to public health officials to teachers and pupils alike. The work purports to have special reference to the tropics but only a very small part—in particular the appendices and a chapter on Diet in India—is not applicable to temperate climates equally. In short most of the work is of general application, though the tropical aspect is kept in view.

There are two additional chapters in the new edition one on Camp sanitation—a short chapter but all the essential points are dealt with, such as choice of site the general lay-out of the camp the securing of a safe and ample water supply and the questions of food and cooking and disposal of refuse. The second addition is a chapter on Social Medicine, written by Dr J. B. Grant, Director of the All-India Institute of Hygiene and Public Health, to whom due acknowledgment is made in the preface.

In a book so excellent and in which so much is included, it comes as a surprise not to find any mention of manganese among industrial poisons, considering the number of important papers on the subject which have appeared in the last five or six years also in work having special reference to the tropics one would expect to see some account of infantile beriberi (which is not the same as beriberi in infants) and of Dr Fehly's work in this connexion. Another disease one misses is sprue and one looks in vain for something about human cysticercosis and hydatid. In fact the only remarks on *Echinococcus* are the brief statement on slaughter-house rules that "Dogs and rats should not be allowed and the slaughterhouse on account of the danger of trichinosis and echinococcus disease." (p. 102) and "*Echinococcus granulosus* is found in the cystic or intermediate stage in the liver and other parts" (p. 415). Under venereal diseases nothing is said of lymphogranuloma inguinale or granuloma venereum or of bejel. No mention is made of the association between herpes and varicella.

So much for omissions—one or two mistakes call for rectification. The Black Death did not occur in the 11th century (p. 484) but in the 14th (as stated correctly later p. 499) the discoverer of *T. cruzi* was not Chaga. If the author has any grounds for perpetuating in edition after edition that "a second attack [of yellow fever] within two years is not uncommon," he ought to produce evidence for a statement totally at variance with the views of those who have had extensive experience of this disease.

Finally a suggestion. It would be a great help to students if the degree of magnification was stated of the worms and insects depicted. From the illustrations one would gather that *Gastrophilus hominis* is much larger than *Fasciolopsis buski* instead of being one-fourth the length, and *Fasciola hepatica*

is depicted as being several times as large as *Fasciolopsis buski*. Among the insects the house-fly is depicted as being larger than *Stomoxys* while *Simulium* insects the house-fly is depicted as being larger than *Stomoxys* while *Simulium* *Stomoxys* and the tsetse fly are all about the same size.

All these are points which could easily be put right and the book remains one to be heartily recommended and in these days of expensive books is remarkably cheap

H. Harold Scott

MOLL, Aristides A. [Ph D Secretary Editor of the Pan American Sanitary Bureau Washington D C etc.] *Aesculapius in Latin America* pp vii+639 numerous illustrations 1944 Philadelphia & London W B Saunders Co [\$7]

As Secretary Editor of the Pan American Sanitary Bureau Washington the author has access to the best medical libraries in the world and he has utilized his opportunities to produce a work of the utmost one might justly say of unique interest. Interesting books may be said to belong to one of three categories (1) Those which may be read continuously from start to finish and which hold one's attention and interest to the end. Often their permanent effect is slight and the work is soon forgotten. (2) Those which produce a more permanent impression and which we turn to and read again more slowly and with greater attention. (3) Those to which we may have to refer in the future and therefore keep always at hand.

The present work by Professor Moll is if not unique very exceptional for it partakes of the characters of more than one of these categories perhaps of all three. To review it really adequately would occupy a whole issue of this *Bulletin* and mere enumeration of the titles of its 78 chapters would fill all the space available for review. We can therefore only touch upon a very few points and otherwise speak in general terms.

The author has dealt with this colossal subject in two main divisions. In the first he writes of times up to the end of the 18th century and in the second from this to the present day. Few people are aware of the richness of the New World in vegetal medicinal plants among them to name only a proportion are *cannabis indica* *carpotroche* *cascara sagrada* *chemopodium coca* *guaiac* *ipocacuanha* *jaborandi* *jalap* *krameria* *sarsaparilla*, and above all *cinchona* and there is little doubt that the American natives were well acquainted with the uses of many of them, their toxic properties their use as diaphoretics as cathartics emetics haemostatics and laxatives. They practised bleeding administered enemata applied poultices made splints of plaster and gums and performed trephining amputations and other surgical operations. Enlightenment had advanced even to the stage of euthanasia for incurables—though euthanasia would seem to be a euphemistic term and a more merciful method might have been found than breaking the back of the unfortunate patient. Cortés had so high an opinion of the skill of native doctors that in a letter to King Charles V he stated that there was no need to send out doctors from Spain. It was thought by many that disease could be got rid of by passing it on to someone else an idea which prevailed in England at least as late as the beginning of the present century when it was a common belief among men with gonorrhoea that they would be cured by passing the infection on to some unsuspecting virgin. It is said that Averroës in 1553 described the circulation of the blood and that Servet (1535) Lobera (1542) Valdés de la Plata (1545) Montaña (1551) and others were also precursors of Harvey and González wrote on *bubas* (jaws) in 1526.

In public health also they went far. The rulers of the Incas made provision at public expense for relief of the poor for cripples for the blind and the aged and in 1524 an ordinance by Cortés required human waste products to be

removed from houses and streets to be cleaned—discharge of domestic waters into the streets was forbidden and all slaughtering of animals had to be done outside the cities. As long ago as 1513 persons were appointed in Porto Rico and Santo Domingo to keep records of births and deaths. After these general matters the author passes on to autochthonous diseases epidemics quarantine, early medical practice and hospitals.

In the second part, designated The Independence Period the author discourses of the developments in medicine and surgery and their various branches and the teaching of them—botany pharmacy dentistry paediatrics, obstetrics, public health, and the rest. A chapter all too short is devoted to medical martyrs many of whom died as a result of attending cases of typhus and yellow fever—the story of Oroja fever *Verruga peruviana*, and Carrón's tragic death is included. The whole work is embellished by numerous illustrations and portraits. There are two invaluable Appendices—one a chronology of diseases, taking each in turn—the second a medical and general chronology for Latin America from 1492 to 1943. There is an abbreviated selective bibliography and there are indexes of names and of subjects.

There are two things which detract somewhat from the great value of this work. First, over-condensation in attempting to get so vast an amount of information into so small a space has resulted in the narrative becoming at times little more than a catalogue of names whole pages here and there consisting solely of names and dates. Second, the irritating interposition of foot notes on almost every page, whereby the continuity of reading is repeatedly interrupted. Delightful though the book is it would be even more readable if the information were less condensed and the footnotes were incorporated in the text. Perhaps it is not too late to urge the author—for fresh editions are certain to be called for soon—to divide the work into two or even more volumes. There is sufficient material for half a dozen at least, each as large as this one reading would be facilitated and the information would be more easily absorbed if accounts were fuller for nearly all the chapters could be much amplified with advantage. Interest would be still further enhanced if more detailed biographies were given of some of the hundreds of persons referred to in the text as men of note.

These are just suggestions and do not detract from the great debt which medical practitioners in the tropics and medical historians everywhere owe to the author for this splendid piece of work.

H. Harold Scott

RAIG Charles Franklin [M.D., M.A. (Hon.) F.A.C.S. F.A.C.P. Colonel, U.S. Army (retd.) D.S.M. etc.] & FAUST Ernest Carroll [M.A., Ph.D., etc.]. *Clinical Parasitology* 4th Edition, thoroughly revised. 871 pp., 305 engravings & 4 coloured pls. 1945 London Henry Kimpton, 25 Bloomsbury Way W.C.1 [50s.]

The fourth edition of this now famous book is bigger than its predecessor by 104 pages yet it remains a handy volume. The print is the same as before, the paper is good, and the illustrations excellent. Apart from additions in the general text, there is a new chapter on the geographical distribution of parasitic infections and in relation to each important parasite there is a separate section on pathogenesis which is a new feature. The book, of course is more than a treatise on the morphology and life-history of the parasites it contains as before, information on the pathology of the relevant human diseases, their symptomatology treatment and control. During the war much new information has been acquired on the subjects with which the authors deal, and in most important respects this new information has been incorporated if it was

available in time. The authors have been closely associated with the teaching of these subjects during the war and have evidently been alert to receive new information.

For instance, the dry and moist forms of oriental sore recently described in Russia, are mentioned. Bullis fever and Colorado tick fever are described. The use of DDT for many purposes and the trials of hyper immune rabbit serum in the treatment of Rocky Mountain spotted fever and of *p*-aminobenzoic acid for typhus are referred to adequately in so far as information was available at the time when the manuscript must have been sent to press. The sections on African trypanosomiasis and *Glossina* however could be improved. The descriptions of the haunts and habits of the various species of tsetse flies and of methods of control are inadequate. The importance of *G. tachinoides* and *G. submorsitans* in transmission and the difference in the control methods for the river-haunting and the non river haunting species are by no means sufficiently stressed. There is no clear statement of the fact that infections with what is usually regarded as *Trypanosoma gambiense* may be as acute as those due to *T. rhodesiense*. Is the remark that *T. gambiense* may be transmitted by coitus worth retaining?

The section on the vectors of malaria is good now that *Anopheles punctulatus punctulatus* has been added all the important species have been included with the exception of *A. melas* but the breeding places of *A. gambiae* (as stated in the table on pp 642-645) give a poor picture of the habits of this mosquito. The vectors of yellow fever are well recorded and in fact throughout the book the lists of vectors and intermediate hosts are very comprehensive. Two small points (page 371) may be mentioned, *Afansonoides longipalpis* and *M. annulipes* are synonyms and the water plant is *Pistia stratiotes* not *stratioides*.

Clinical Parasitology is to be recommended as a reference book and as a textbook to teachers research workers and students alike. It is of the very highest quality.

Charles Wilcocks

BIESHEUVEL S [M.A.(Cape Town) Ph.D (Edm)] *African Intelligence* pp viii+225 12 figs. 1943 Johannesburg South African Institute of Race Relations P O Box 96 [7s 6d]

The title of this book is a sufficient indication of the importance of the subject with which it deals. Whether we start with certain prepossessions about the intelligence of the Africans or with none at all we must admit that as an academic, and as a practical issue it is one of the most important of our day. It should be noted at once that African in this sense means only Africans in the Union of South Africa. No other Africans are referred to in this study and readers who know other parts of Africa have to be constantly checking their reactions to some of the statements and reminding themselves that this is a study in a strictly limited field.

The book originated, as the author explains in his preface from an attempt to review a monograph by Dr L. Fick of the South African Council for Educational and Social Research on 'The Educability of the South African Native'. Fick's main contention was that the mental age of the Africans in the Union was from 4-5 years below that of the Europeans and that the observed inferiority was permanent and innate and not due to preventable environmental influences. Dr Biesheuvel found that a critical examination of this monograph raised so many issues that he had to deal systematically with each problem. Hence his review grew into a book which has all the freshness and drive of a challenge and yet has preserved an essential scientific objectivity. He achieves this by relegating to his final chapter any detailed analysis of Fick's work and by concentrating all the rest of his book on an examination

of the issues involved in comparisons of intelligence on an inter racial basis. It is unfortunate that there is no index to this otherwise well-documented work.

In a brief survey of the leading authorities on the nature of intelligence he lays down as an essential preliminary that "any study of African intelligence particularly if the comparison with the intelligence of Europeans is its chief object, will have to make some choice between the different theories of intelligence now in the field. Arising out of this as a starting point he asserts that intelligence test scores are on the whole of less importance than mental processes and their attributes and antecedents. Two practical issues are then stated, which recur in different forms throughout the book, and which are of far wider import than their occurrence in the Union of South Africa—the formulation of educational policies for Africans and the adjustment of Africans to and their future development in western civilization.

The main chapters of the book fall into two parts. The first deals with the measurement of intelligence the problems of sampling the effect of the cultural milieu on test-intelligence and the suitability of existing tests for measuring African intelligence. The second half reviews the factors of home environment school and nutrition in their effect on intelligence.

In the earlier chapters there are two leading scientific problems which are of wide interest. The first is the question what do intelligence tests measure? Dr Biesheuvel's answer is We are compelled, therefore to look upon an intelligence test score not as a direct measure of innate ability but as a measure of hereditary potentiality as it happens to have been realized by specific environmental circumstances. The latter half of the book is from this point of view an examination of selected environmental circumstances analysing their effect on the growth of intelligence. The second main problem is that of the control group. Dr Biesheuvel considers that in previous inter racial intelligence studies in South Africa control groups have been chosen where the factors of nutrition and home and school environment have not been equalized. He raises indeed the question of whether the environmental differences are not so great between Africans and Europeans in the Union that the matching of two representative and parallel groups is impossible. He shows how difficult it is to select representative samples of the African population which cannot be done with any accuracy on a basis of division into urban and rural, tribal and detribalized. He discusses such difficulties as the unfamiliarity of the Africans with the test situation and the speed factor in the tests which is based on a peculiarly Western European sense of time and

hurry. His conclusion at this point is that current attempts to measure inter racial intelligence are premature and all further work on these lines will inevitably be unscientific until further research has been made into the "abilities response mechanisms and manner of thinking and feeling of the Africans. Two examples of such research by Nel and Endeman which he quotes and commends are both unfortunately published in Afrikaans and are therefore virtually inaccessible for consultation by most medical and educational research workers outside the Union.

In examining the effect of home environment on the growth of intelligence the research worker in the Union is placed in a peculiarly difficult position. As Dr Biesheuvel points out African tribal family life develops intelligence in directions almost entirely different from those of the European home. The home environment in tribal society conditions the growing child to become a member of a group where formerly the standards of skills ability and behaviour were laid down by tribal codes and sanctions. In certain remote parts of Africa such tribal society can still be found, but it does not exist anywhere in the Union in an untouched form in spite of the policy of segregation. White

and black society are bound together by economic links which stretch from the towns and industrial centres into the interior of the reserves. Hence in the Union there can be no measurement of intelligence as developed under purely tribal conditions to serve tribal purposes. Dr Biesheuvel decides on other grounds that tribal Africans will have to be excluded from the experimental group for the reason that there can be no parallel European control group with which to compare it. But a very fundamental difficulty then arises. In comparing the home environment of urban Africans with urban Europeans many of the material features of the home may have certain similarities but the general cultural milieu in which the African child is brought up in the cities is neither African nor European. It is a hybrid culture which has not yet been sufficiently studied in any of its aspects sociological economic or psychological so as to provide accurate factual data for measuring home environmental factors. Dr Biesheuvel says emphatically that home environment can only be equated within the same cultural milieu and it is evident to any social research worker that living in the same city does not necessarily produce a similar cultural milieu. Moreover his conclusion after examining such social economic studies of urban African conditions as are available is that the average urban African home environment is bound to stunt very markedly the growth of intelligence of the children reared in it not only by failing to provide those stimuli which alone would enable the most to be made of innate potentialities but also by creating situations which have an adverse effect on such growth as might spontaneously occur.

To all workers in tropical areas the relation of malnutrition to the growth of intelligence will be of great interest. Dr Biesheuvel points out two major difficulties in assessing this particular environmental factor. He considers the clinical method of judging malnutrition as too elaborate for use with large groups and rejects the height weight ratio as being discredited. That leaves us at the present stage without a valid practical method of judging malnutrition. The second difficulty in his view is the inconclusive nature of the evidence that subject to particular conditions the growth and function of the nervous system can be impaired by malnutrition. As a result of reviewing a number of authorities however he comes to the conclusion that qualitative malnutrition if severe permanently impairs intelligence at all age-levels and hence he urges that in measuring intelligence some control should be exercised over the nutritional condition of the experimental group.

The results of diet surveys of Africans in urban areas though so far not correlated with intelligence testing show such a general low level of nutrition that comparisons could only be made with the very lowest income levels among Europeans—that is among the most depressed section of the urban European population. This group as Dr Biesheuvel says would be useless for control purposes in an inter racial study as it would probably represent a genetically inferior sample of the European community.

The result of this analysis is a somewhat negative conclusion. Dr Biesheuvel says categorically that under present circumstances and by means of the usual techniques the difference between the intellectual capacity of Africans and Europeans cannot be scientifically determined. One cannot environmentally equate an African group with a European group without selecting unrepresentative samples.

It is interesting to note that Dr Biesheuvel's doubt about the representative character of samples of the African and European population is in line with a conclusion reached in the United States of America. In 1934 the *Journal of Negro Education* gave a whole number (Vol. III No 3) to a critical summary of the studies on the relative physical and mental abilities of the American Negro. It was recognised that the difficulty of getting fair samples was one

of major importance, and this difficulty was practically insuperable in the southern States, the area where the racial situation shows the nearest parallel to that in the Union. It was stated categorically that "it is impossible to secure fair samplings of Negro and white children of the same age who are equally advanced educationally and have had similar environments."

Must we therefore accept a non possumus? As far as the Union of South Africa is concerned, the dust of the battlefield obscures the main issues. On both sides black and white, emotional attitudes will enter into any attempt to make comparisons of intelligence on inter-racial lines. Too much is at stake in such a study which is directly bound up with the economic and political development of the country. That is no reason however why in other parts of Africa studies should not be made of the various environmental influences and their effect on the growth of intelligence without bringing in the factor of comparison with Europeans. Casual statements are made often about a particular tribe being so intelligent. Dr Baeshevel himself refers to such a statement about the Basuto as being intellectually superior to other tribes. As they are outside the Union politically though closely linked with it on economic grounds, they have not been included in any of the surveys reviewed by Dr Baeshevel. He asks the question which has constantly puzzled many people in Africa, whether statements about the intellectual superiority of any tribe can be substantiated. He thinks that intelligence tests could be applied to such a problem. Here is an obvious field for a combination of research techniques for the psychologist will need the help of the sociologist and the doctor in the assessment of the home environment and the nutritional factors. It may be unimportant in the scientific field whether certain tribes are proved by such tests to be more intelligent than others. Dr Baeshevel thinks that these popular beliefs are unfounded, though until proof is forthcoming no one can make positive statements on the subject. What is however of great importance in the scientific field is the working out of joint research techniques between psychologists, sociologists and doctors. The problems connected with the development of Africa and its peoples particularly in the sphere of education and intellectual advance, cannot be solved by a number of unrelated approaches.

Margaret Read

HARPER, F. *Extinct and Vanishing Mammals of the Old World*. pp xv+850
67 figs. & 1 pl. [Bibliography] 1945. Special Publication No. 12.
American Committee for International Wild Life Protection New York
Zoological Park, New York 60 N.Y. [30s.]

The present book is briefly noticed because of the relation of game animals and game extermination to tsetse flies. The volume consists of a relatively brief introduction which explains how the information has been collected and points out the great variety of factors which have caused the disappearance or increasing scarcity of many species of mammal in the Old World. It contains a chronological list showing the approximate dates (generally to a half-century) of disappearance for each continent separately.

The greater part of the book consists of an account of many species arranged under Orders. Some of these species have disappeared or are in grave danger of doing so but some of them as it appears to us are not at the moment greatly reduced or on the danger list.

[No. 6

SUMMARY OF RECENT ABSTRACTS *

V LEISHMANIASIS

GENERAL.

KIRK (p. 180) discusses the evolution of the leishmania infections of man pointing out that although three main types of disease are recognized there is no hard and fast line of demarcation between them. He notes that in the Sudan cases are seen in which the three types merge into or follow one another so that there may be difficulty in differentiating between oriental sore and a primary lesion of kala azar or between muco-cutaneous leishmaniasis and the mucosal lesions of a post kala-azar condition. The reason for these variations is that there exist different strains of the parasites which probably have different virulence and tendencies. The leishmania of kala azar in India the Sudan and the Mediterranean are not identical in all respects—for instance post kala-azar dermal leishmaniasis is common in Bengal but rare in Assam—and there are two well-marked types of oriental sore in Turkestan. KIRK (p. 875) noticed that a monkey which had been inoculated with a strain of leishmania after passage from a human case of kala azar (in the Sudan) through two other monkeys developed lesions resembling those of espundia. Similar lesions occasionally occur in human kala azar in the Sudan and may be due to the characteristics of certain strains of leishmania.

JONES *et al.* (p. 543) describe the successful cultivation of leishmania in the yolk sac of developing chick embryos.

SENERJIE and LEWIS (p. 977) have devised a slide agglutination test with antigens from cultures of the various leishmania, and serum from rabbits immunized first with killed cultures and later with living cultures. Homologous leishmania are agglutinated to high titre and heterologous to lower titres. It seems that this test may be useful in the diagnosis of human disease.

VISCERAL LEISHMANIASIS.

SHORTT (p. 100) has written an account of recent research in kala azar with special reference to Assam.

Epidemiology

In Tashkent kala azar shows a remarkable focal distribution within the towns in spite of the fact that sandflies are uniformly distributed throughout

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v. 42. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

the endemic regions. KHODUKIN (p 356) attributes this to the existence of reservoir hosts, especially dogs and he supports this view by aetiological, clinical and epidemiological evidence, noting particularly that whereas in man the parasites are soon eliminated from the peripheral circulation in dogs they are first present in the extensive multiple papules on the muzzle and later become generalized in the skin. The dog, therefore is held to be the principal reservoir of the disease though there is some evidence of transmission from man to man, and from man to dog. *Leishmania* have not been found in rats mice or lizards. BATTELLI *et al* (p 977) have found *leishmania* in the spleen and bone marrow of dogs in Eritrea, and FERRO LUZZI (p 100) notes that kala azar is endemic in the lowlands of Eritrea.

SEN GUPTA (p 542) has enquired into the epidemiology of kala azar in Bengal during the period 1831-40 and notes that the distribution of the disease is very unequal. For the whole of Bengal there has been an incidence rate of 210 cases each year per 100 000 of the population—this is so high that the disease still constitutes one of the grave medical problems.

SCOVILL (p 875) has written an account of kala azar in China. The point he particularly makes is that the incidence of the disease has increased considerably as a result of disturbances occasioned by war. Kala azar is common in the north but is almost unknown in the more tranquil south, and the Chinese hold that it follows in the wake of famine, flood and war. CLOW (p 101) describes kala azar in the Province of Shensi, China, where the disease has now become almost epidemic and constitutes a serious problem. Sandflies abound in the months of May and June. It is most common in children and young adults and conforms to the classical type. Treatment consists of administration of various antimonials and of stilbamidine but of 400 patients only 31.5 per cent. were cured or doubtfully cured and 16.3 per cent. relapsed, were moribund or died.

Aetiology Transmission

SENEKJIE (p 359) after a review of available information concludes that the agent of S. American kala azar which at first was known as *L. chagasi* is identical with *L. donovani*.

ARMYTAGH and BOLLIGER (p 358) have infected a young opossum, while still in the maternal pouch with *L. donovani* by intraperitoneal injection.

MALONE and BROOKS (p. 357) argue that the sandfly transmission of kala azar in India has not been satisfactorily established and quote evidence which, in their opinion is against this method. For details the original abstract should be consulted. In comment WENYON expresses the view that the authors have not refuted the sandfly theory which is receiving increasing support both for kala azar and oriental sore.

Clinical Findings.

LOWE (p 711) discusses the early diagnosis of kala azar noting the characteristic feature of irregular fever with rapid pulse but without symptoms of toxæmia. The only other early findings are a positive result with the complement fixation test in which the W.K.K. antigen is used [see SEN GUPTA below] and the presence of *leishmania* in sternal puncture material. One condition is essential for early diagnosis namely that the possibility of kala azar should be kept in mind.

BURCHINAL and WOODS (p 635) describe three cases of kala azar in U.S. soldiers who had served in N. Africa and Sicily. In one the only sign was enlargement of lymph glands particularly of the neck. Biopsy confirmed the diagnosis. Treatment with sodium antimony gluconate was given in all these

cases with success stillbamidine was not useful in two of them. ANGEVINE *et al* (p 976) report another case in an American soldier who had served in N Africa or Sicily in which the only sign of kala azar was enlarged lymphatic glands in which the parasites were seen. They describe the histological features of the glands.

If serum from cases of kala azar is kept at 7-11°C for three days a precipitate is formed. WERTHEIMER and STERN (p 262) show that this is due to a substance allied to euglobulin which they have named the Cold Fraction. This phenomenon persists for long periods after clinical cure and it is not yet known whether in such cases cure can be regarded as complete. The fraction is present in certain other morbid conditions.

SEN GUPTA (p 358) gives an account of the use of the complement fixation test with the Witelsky-Klingenstein and Kuhn antigen, for the diagnosis of kala azar. It is usually positive in kala azar and usually negative in other conditions which might be confused with it and is very useful for early diagnosis.

Treatment

Sodium antimony gluconate (Stibatin Glaxo Laboratories) was used for the treatment of kala azar by BURKE and CHARRAVARTY (p 17) with success in each of 21 cases. It is supplied as a solution of which 1 cc contains 20 mgm. of pentavalent antimony. The daily dose is 1 cc. for each year of age with 15 cc. as the maximum and as much as 100 cc may be given in 7 days by intravenous or intramuscular injection. There were no unpleasant reactions in this series. FERNÁNDEZ CASTAÑYS (p 978) again writes of the successful results obtained in infant kala azar by the use of sodium antimony gluconate suspended in oil and given by the intramuscular route. He thinks that this is the method of choice.

SARROUY and GILLOT (p 101) report favourably on Pentastib (the methyl glucamine salt of para amino-phenyl-stibonic acid) and state that the best results in infant kala azar were obtained when the quantity to be administered was spread over the minimum number of days—viz for each kgm. of body weight 0.07 gm should be injected daily for 4 days or 0.1 gm. daily for 3 days. PATEL (p 263) reports so favourably on Stibatin in kala azar that he regards it as the drug of choice. It has many advantages over neostibosan and urea stibamine. He obtained cure in each of six cases treated.

SEN GUPTA (p 543) reports cases of mixed kala azar and malaria. Antimonials do not affect malaria parasites and quinine does not affect leishmania, but there seems to be a certain antagonism between the infections.

It is known that when stillbamidine solution is kept and especially if it is exposed to light changes occur which render the substance more toxic. Late sequelae of stillbamidine treatment observed by KIRK and HENRY (p 18) were effects of the nervous system (changes in sensation along the course of the trigeminal nerve neuritis of the nerves of the leg rarely epilepsy or mania) or fatal delayed poisoning in coma. These effects did not develop until 1-3 months after the completion of treatment. Stillbamidine is absorbed quickly by the tissues and is released slowly for excretion and as HAWKING points out in comment is in this respect similar to mepacrine. Evidence accumulated that the toxic symptoms were due to chemical changes in the drug which occur when solutions are exposed to light.

FULTON (p 19) has investigated the therapeutic action of certain newer aromatic diamidines on *L. donovani* infections of hamsters. For details the original should be consulted. FULLER (p 264) writes of a colour reaction for aromatic diamidines previously described by DEVINE to which he has made certain modifications. Details are given in the original abstract.

FULTON (p. 978) found that penicillin had no action in experimental infection of hamsters with the leishmania of Indian kala azar.

GOODWIN (p. 262) in a critical examination, has shown that examination of smears from the cut surface of the spleen of animals infected with *L. donovani* and counting parasites against cell nuclei, is a reliable method of estimating the progress of the disease and the effect of treatment. It is necessary however to count up to 1 000 cell nuclei if the numbers of leishmania are small in order to obtain a reliable result. The organisms are fairly evenly distributed through an infected spleen.

CUTANEOUS LEISHMANIASIS ORIENTAL SORE

General Treatment

FAROOQ and QUTUBUDDIN (p. 978) have found oriental sore in as many as 42-68 per 1 000 of the population in part of Hyderabad State the majority of cases were in children under 10.

ELKERTON (p. 543) notes that most of the cases of oriental sore in an Indian Military Hospital were in members of a cavalry unit, or in men engaged in transport and therefore associated with horses. He thinks, therefore, that *Stomoxys calcitrans* may be implicated in transmission. Treatment of these sores by scraping under general anaesthesia, and subsequent dressing with tannic acid powder was successful, but the injection of atabrin was tried and was found to have certain advantages.

KOJEVNIKOVA (p. 454) has found that the most type of oriental sore tends to occur on the limbs and the dry type on the face. The same author (p. 878) describes cases in which oriental sore developed at the site of existing trauma of the skin, and hazards the opinion that sandflies are attracted to such areas in preference to intact skin.

BERBERIAN (p. 877) has shown experimentally that dogs can be infected with *L. tropica* with the development of cutaneous lesions, but not of visceral lesions. The skin lesions of dogs in nature, which are sometimes attributed only to kala azar may in fact be due to oriental sore.

BAKHIRAMI (p. 454) describes the technique of cultivating *L. tropica* in the chick embryo.

BALL and RYAN (p. 19) quote their experience which shows that Neostam (Burroughs Wellcome & Co.) is very effective in the treatment of oriental sore. Intravenous injections are given twice each week, and increase from 0.05 to 0.2 gm each to an average total of about 1.14 gm. Toxic reactions may be reduced by giving the injections at noon and withholding the midday meal, or they may be controlled by morphine. In 231 American soldiers thus treated, there were no failures. The average time for cure was 14.5 weeks. Neostam seems to be the most effective means of treatment of oriental sore.

KLITZNER (p. 455) treated oriental sore with sulphacetamide, and thinks that this drug had some specific action apart from its effect in eliminating secondary bacterial infection.

GUPTA and KAHALI (p. 191) have made a pharmacological study of umbellatine, which is derived from *Berberis* and is allied to berberine. It apparently has a useful action in the infiltration treatment of oriental sore.

Immunity

BERBERIAN (p. 102) states that the immunity eventually produced by an oriental sore which heals is complete, but he has shown by experiments in man that it takes a long time to develop about 240 days after inoculation of infective material. During this period, therefore, sores additional to the

deliberately produced sore may be acquired. Immunity does not develop until the papule ulcerates and commences to heal and the leishmania disappear naturally from the lesion. He (p. 359) has previously found that the incubation period after injection of cultures of *L. tropica* was 2 weeks to 6 months but he now quotes three cases in which this was as long as 18 to 56 months.

The same author (p. 360) has shown that suspensions of cultivated *L. tropica* in isotonic saline will remain viable for 17 days at temperatures varying from 15.8° to 38.3°C. This observation was made to meet the need of physicians who require suspensions for purposes of immunization.

BERBERIAN (p. 360) has attempted to confirm previous work by PESSÔA and PESTANA, who claimed that inoculation of *L. tropica* killed by phenol would produce immunity to oriental sore. His results were entirely negative and no immunity to infection was found in two persons so inoculated though immunity was proved in others who had recovered from sores produced by the injection of living flagellates.

KATZENELLENBOGEN (p. 361) has followed up the results of vaccination in 416 people near the Dead Sea in Palestine where oriental sore is hyperendemic. The incubation period varies from about 2 weeks to 18 months. In 45 persons a febrile reaction occurred probably allergic in nature but in only four of these did a vaccination sore develop. In 27 others no vaccination sore followed though they had no evidence of previous oriental sore the possibility of natural immunity is to be considered. The vaccination campaign has produced very favourable results of 25 persons newly arrived in the district and vaccinated none has had a natural sore in a period of 2 years whereas of 70 not vaccinated 65 have had sores in the same period.

MUCO-CUTANEOUS LEISHMANIASIS (AMERICAN)

KEAN (p. 359) states that an endemic focus of cutaneous leishmaniasis has been found in Arraiján, Panama, and describes the clinical features of the disease. A striking feature in several cases seen in the Gorgas Hospital during the present century has been nodular lymphangitis in areas draining the ulcers. Treatment with antimony potassium tartrate or Fouadin is successful. STEWART and PILCHER (p. 712) report a case which they claim to be American muco-cutaneous leishmaniasis, in a boy who had never left Texas.

COSTA (p. 544) describes American leishmaniasis in which the lesions may be mistaken for those of yaws.

LOPES and LAENDER (p. 979) have found that the Montenegro skin test is the method of choice for the diagnosis of mucocutaneous leishmaniasis in the clinics and health centres of the interior of Brazil.

BELTRÁN (p. 361) has found it impossible by reducing the pH of culture media below 7.2 to eliminate bacteria from cultures of *L. brasiliensis* without killing the leishmania.

PIFANO (p. 191) gives a list of sandflies which may be vectors of *L. brasiliensis* in one region of Venezuela.

PESSÔA and VILLELA (p. 712) report favourably on the results of treatment of American muco-cutaneous leishmaniasis with the German preparation Antimon-ditoxin which appears to be more useful than tartar emetic and Fouadin. SNOW (p. 544) had no success in the treatment of a case of American cutaneous leishmaniasis with penicillin.

MALARIA

AUSTRALIAN MILITARY FORCES Malaria in the Borneo Operations May 1-
 Sept. 1 1945 [ENGLISH J C. Lt. Colonel Malarologist Adv H.Q
 AMF] RFA (46) 4 16 mimeographed pp [Med. 5/1]

— Destruction of Adult Mosquitoes in the Early Stages of an Operation
 [MACCALLUM W P Brigadier DDGMS Adv L H Q] Technical
 Circular No 4 1945 June 6 4 mimeographed pp [Med. 45/195/172.]

The incidence of malaria was low in Tarakan After the landing very few anophelines were found *A. kochi* was most in evidence. Only two *A. leucosphyrus* breeding places were found and only one adult *A. umbrosus* was captured The island is small its population was static and mostly congregated near the controlled areas of the oil wells and the port. None of 325 children examined had an enlarged spleen and only two of 220 children harboured malaria parasites, *P. vivax* in each case. Among 600 adults the only positive blood films obtained during a 2 week period were *P. vivax* 21 *P. falciparum* 9 and *P. malariae* 1 all the parasite carriers were Indonesian labourers imported from the mainland by the Japanese

In Labuan Island before the war mosquito control measures had been limited to an area of 2 square miles in the town of Victoria The common mosquitoes were *A. kochi*, *A. barbirostris*, *A. hyrcanus*, *A. sundaeus*, *A. leucosphyrus*, *A. tessellatus*, *A. karwari*, *A. separatus*, *A. umbrosus* and *A. philippinensis*. After the arrival of the Japanese mosquito control practically ceased the tide gates were broken and *A. sundaeus* breeding became common in the town area Detailed information is lacking regarding the incidence of malaria before the war but *P. falciparum* malaria was said to be rare and cerebral malaria almost unknown The Japanese imported heavily infected Javanese labour and used people who had previously lived in a controlled area for clearing and cultivation Malaria became rife At the time of the allied landings the spleen rate in Malay children was 75 per cent During the first 3 weeks of July some 1100 of the 8000 local natives were treated for malaria amongst whom there were eight cases of cerebral malaria and one of blackwater fever

In Brunei town malaria had been severe prior to 1935 An antimalaria organization was established in that year and by 1939 the spleen rate in 561 children in the river kampong had been reduced to 1 per cent On the arrival of the Japanese the inhabitants of the river kampong fled to the hills and the rice-growing districts some 60 per cent of them contracted malaria there. They drifted back malaria control in the town was discontinued and the incidence of malaria increased The Japanese also suffered severely some of them dying from cerebral malaria *A. kochi* was the commonest mosquito in the town *A. leucosphyrus* and *A. barbirostris* were common in the outskirts. In Kuala Beluar Seria there was considerable malaria in 1932 The land was covered with swamp forest with a narrow sandy coastal strip. The vector was *A. umbrosus* *A. sundaeus* was not common. As clearing proceeded the latter species replaced the former as the chief vector Antimalarial work increased in efficiency and there was but little malaria from 1939 to 1941 Other species of mosquito found in this area were *A. kochi*, *A. tessellatus*, *A. separatus*, *A. maculatus*, *A. karwari*, *A. leucosphyrus* and *A. basalis*. All organized antimalarial work ceased after the Japanese occupation in December 1941 There was an increase of *A. umbrosus* and later of *A. sundaeus* breeding Native labour was recruited from highly malarious inland villages. In 1944 the malaria rate was higher than it had ever been, even before control work.

Malaria

Malaria

Most of British North Borneo was highly malarious. blackwater fever was not uncommon among Chinese and Malays. Dr MACARTHUR found *A. leucosphyrus* to be the chief vector in N W Borneo. it breeds in thick jungle. *A. maculatus* is considered to be unimportant. *A. umbrosus* and *A. hyrcanus* are said to have been incriminated in certain parts. In Weston spleen rates of 55 and 54 were found in Malay and Chinese children respectively. But little information was available about pre war malaria in the town was well controlled but the situation after the occupation was not clear.

The incidence of malaria among the troops was low. It is not possible to sum up the results of the survey as it was too preliminary. The incidence of malaria among the troops was low.

The incidence of malaria among the troops was low. A parasite survey of 277 natives showed 17 and *P. falciparum* 24. Of great interest is the information given concerning the destruction of adult mosquitoes by drifting mists. Two types of mist were used pyrethrum spray from aerosol dispensers. Freon bombs mostly used indoors in intact or partly destroyed houses tunnels closed pill boxes etc but their outside use was also tried. The dosage varied from 4 to 12 seconds spraying per 1 000 cubic feet. The measure was effective especially against *Aedes* mosquitoes. The outside use of Freon bombs was advanced against *Aedes* mosquitoes. The measure was effective especially in areas of jungle and scrub where *Aedes* were prevalent. The method adopted was that of walking along bush tracks at the rate of a yard a second with a discharging dispenser in either hand or of placing them on the ground at 15-yard intervals and allowing them to discharge for 60 seconds at each location.

Five per cent DDT mist was used only out of doors. The equipment was an American 3-mil. Rega portable sprayer.

Five per cent DDT mist was used only out of doors. The most satisfactory equipment was an American 3-gallon decontaminator pressure sprayer with a Rega nozzle of 0.08 in aperture. As a means of control against dengue fever this method appeared to be of the greatest use. The camp area in which a case of dengue occurred including an area of 100 to 200 yards around it was thus sprayed. The use of DDT applied to walls, tents, mosquito nets, etc., had a marked effect proved its value. For larval control, the use of DDT in the form of a 1 per cent solution in water, allowing them to discharge for 60 seconds at each place, was found to be of placing them on the ground.

The use of DDT applied to walls tents mosquito nets etc. for residual effect proved its value.

For larval control in service conditions the use of plaster of paris and saw dust pellets soaked in 5 per cent DDT in oil was very convenient and effective. Two parts of sawdust and one part of plaster of paris by volume are mixed with water and allowed to set. The mixture is then cut into pellets of from half to one cubic inch and allowed to dry (48 hours). The pellets are then soaked in 5 per cent DDT in oil for a further 48 hours and are then ready for use. Their effectiveness was 100 per cent. for 2-4 weeks in suitable breeding places. They may be thrown a considerable distance to breeding places difficult of access and are ideal for collections of water in bomb craters tanks drums etc. while their use in ricefields is harmless.

The use of suppressive mepacrine prevented mal-
as an index of the efficiency of the treatment.
The very low incidence of malaria in the area was maintained.

The use of suppressive mepracine prevented malaria incidence being used as an index of the efficiency of mosquito control in the Borneo operations. The very low incidence of dengue however among susceptible troops landed in areas where dengue is endemic is strong evidence of the efficiency of that control. During the first 10 weeks of the operations there were 44 cases of

[June 1948]

dengue in Tarakan, 208 in Brunai Labuan and 85 in Balikpapan. At the end of 10 weeks very few cases were occurring in any area. The lowest incidence of dengue occurred in the area where most use was made from the earliest days of ground spraying with DDT mists, particularly in camps in which dengue had occurred.

The incidence of malaria was surprisingly low. Up to the end of September only 114 cases of *P. falciparum* malaria had occurred, 55 in Balikpapan, 35 in W. Borneo, 4 in Morotai and 0 in Tarakan, among forces totalling 57 000 during an average period of 12 weeks. Norman White

PAL, R. On the Bionomics of *Anopheles culicifacies* GÜM. Part II. The Ecology of the Immature Stages. *J. Valaria Inst of India*. 1945 June, v 6 No. 1 53-74 1 fig & 1 chart 24 rels)

Part I of this paper was concerned with the longevity of *Anopheles culicifacies* (this Bulletin 1944 v 41 448). In the second part the author discusses the results of his laboratory experiments on the aquatic stages of the mosquito and compares them with observations made in the field. It is known that *A. culicifacies* breeds in irrigation channels, pools in river beds, borrow pits and cement tanks and that it can adapt itself to almost any type of water. Experiments showed that there was no consistent preference for any particular type of water. Ovipositing females avoided soapy water, polluted stagnant and distilled water. The author concludes that eggs are scattered at random, and that this accounts for the presence of *A. culicifacies* larvae in all kinds of breeding places.

Experiments to discover the time of oviposition showed that 60 per cent. of eggs were deposited between 18-00 and 22-00 hours, 27.9 per cent. were laid between 22-00 and 01-00 hours and 12 per cent. between 01-00 and 04-00 hours. Thus, egg laying continued throughout the hours of darkness but most were laid during the first third of the night. The number obtained in these tests varied very little from season to season. The number obtained in these tests is given as 115 to 134.

In the laboratory, ovipositing females showed slight preference for cooler water when given a choice between 38°C. (102.4°F) and 42°C. (107.6°F) between 38°C. and 45°C. (113°F) however the warmer water was definitely avoided. Eggs larvae and pupae exposed to constant temperatures between 28°C. (82.4°F) and 32°C. (89.6°F) with the optimum development was between 28°C. (82.4°F) and 32°C. (89.6°F) for eggs 45.5°C. (113.9°F) for fourth stage larvae and 43.3°C. (109.9°F) for pupae.

In small natural breeding places the maximum surface temperature during the hot summer months was rarely as high as 44.8°C. (112.6°F) but 43°C. (109.4°F) was common. In large ponds it rarely rose above 37°C. (88.6°F). In May and June therefore *A. culicifacies* deserts the hot pools and channels and resorts to the cooler wells and tanks. In December and February the maximum water temperature ranged between 10°C. (50.0°F) and 15°C. (59.0°F). At such temperatures the life-cycle takes about three months. In the laboratory eggs were killed at temperatures below 10°C. and most larvae and pupae died when kept at 5°C. or below.

Results obtained from a long series of experiments to investigate the effects of free and saline ammonia on oviposition and on development of larvae showed

that female *A. culicifacies* laid eggs indiscriminately in concentrations as high as 120 parts per million but that larvae ceased to develop in concentrations exceeding 12 parts per million. This may partly account for the absence of this anopheline from highly ammoniacal waters.

The effect of organic pollution of breeding places was studied by preparing specially polluted water in the laboratory, withdrawing samples at intervals for analysis and allowing gravid females the choice of ovipositing in the withdrawn samples. The females and the immature stages were seen to be fairly sensitive to organic pollution. If it exceeded 1064.50 parts per million females were repelled and larval development ceased.

From several experiments designed to investigate the effect of light and shade on oviposition the author's conclusion is that shade itself had no appreciable influence but females were sometimes unable to lay eggs because of the mechanical obstruction caused by the object producing the shade.

Figures relating to the experiments are set out in 13 tables in the text and in five appendices.

Malariaologists and entomologists will find this paper a useful contribution to our knowledge of the bionomics of an important mosquito.

RAO T R. Behaviour of *Anopheles fluviatilis* Part III. Larvae Habitats in North Kanara District. *J Malaria Inst of India* 1945 June v 6 No 1 77-82.

Nocturnal movements and day time resting habits of *Anopheles fluviatilis* were dealt with in Parts I and II of this series of papers [this *Bulletin* 1944 v 41 641 1945 v 42 625]. This third paper discusses 9,526 collections of *Anopheles* larvae made in the North Kanara district by the Bombay Provincial Malaria Organization between August 1942 and December 1944.

With the object of obtaining more precise information regarding the breeding places of *A. fluviatilis* the collection figures were analysed and are presented in two tables.

Altogether 2,557 larvae of *A. fluviatilis* were collected and of this number 1,678 (65.6 per cent.) were from streams and channels. There were 3,816 searches in streams and channels and 493 (13.6 per cent.) yielded *A. fluviatilis* larvae. Out of 797 searches in fallow rice fields, 42 (5.3 per cent.) and out of 1,386 in growing rice fields 102 (7.4 per cent.) yielded *A. fluviatilis* larvae. The species was more prevalent in rice fields in 1944 than in the earlier period. Out of 157 searches in swamps 40 (25.5 per cent.) produced larvae of this species though this type of breeding place was relatively uncommon, small and easily dealt with it should not be ignored. The *kutcha* field wells situated in rice field valleys were also found to be breeding *A. fluviatilis*.

Thus while it is confirmed that streams and channels are the generally preferred breeding places of this anopheline the author suggests that intensive studies may reveal that *A. fluviatilis* breeds in rice fields, swamps and wells more commonly than has been believed and that these places may in some localities be more important even than streams and channels.

ZOLOTAREV E K. [*Anopheles maculipennis* of Northern Iran.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 2 50-57 1 map [In Russian.]

This paper deals with the distribution and ecology of *Anopheles maculipennis* in Iran. The identification of subspecies was based on the eggs laid by captured females 5,000 of which produced 1,000 batches of eggs.

was found that along the Iranian coast of the Caspian Sea, *A. maculipennis* is represented by three subspecies: *typicus*, *subalpinus* and *sacharovi*. *A. m. maculipennis* occurs at the foot of the northern slopes of Elburz and on the eastern slopes of Bagrov Dag and Talish, as well as along a narrow strip of low lands on the west and east coast. *A. m. subalpinus* is also characteristic for the maritime plains of Sefidrud and Babol while *A. m. sacharovi* inhabits the steppe zone of the eastern Caspian lowlands and is not found to the west of the town Babolser. As regards the ecological requirements of the different subspecies of *A. maculipennis*, *A. m. maculipennis* is associated with waters originating in the mountains occurring both at high altitudes and in basins of rivers fed from mountain sources. *A. m. subalpinus* is found in standing waters of the humid maritime lowlands and in rice fields while *A. m. sacharovi* occurs only in waters of high salinity in the arid steppes. C. A. Hoare

HEILIG R. *Malaria in Diaguia. Indian Physician* 1945 Nov v 4 No 11 237-43

This address deals with many pathological conditions that malaria infections may simulate and some interesting illustrative cases are recorded. The combination of malaria with pneumonia is serious but sulphonamides and quinine or atabrin can be used simultaneously without giving rise to any untoward effects. A case is recorded which suggests that pleurisy with effusion may be caused by malaria. A patient in whom the symptoms had suggested a diagnosis of coronary thrombosis was found to have a heavy *P. falciparum* infection and was cured with quinine. Malaria may closely simulate amoebic hepatitis, and malaria attacks occasionally present all the features of gall-stone colic. The case history of a patient in whom malaria seems to have caused a pylorospasm of allergic origin is of interest. Malarial dysentery, malarial nephritis and malarial ascites are discussed. Cerebral malaria may begin, and end fatally without any rise of temperature. Persistent hiccup may occur in acute as well as in chronic malaria and only yields to antimalarial treatment. The address ends with the warning that even the heaviest malarial infection does not exclude the possibility of a co-existing appendicitis, puerperal sepsis or urinary tract infection. Norman White

THONNARD-NEUMANN E. Zur Pathogenese der Malaria Anämie. (The Pathogenesis of Malarial Anaemia.) *Deut. Tropenmed. Ztschr.* 1944 Apr-May v 48 Nos 7/10 129-47 4 figs.

The author studied the blood and bone marrow in 34 cases of malaria of which 26 were *P. vivax* infections, 7 *P. malariae* and 1 *P. falciparum*. Five cases were natural infections, the rest were induced, all but three by means of blood injections. The patients were allowed 10 paroxysms and then treated with quinine, atabrin or a new preparation. The clinical picture varied widely: the *P. falciparum* case was fatal.

Daily blood parasite and reticulocyte counts were made. Red blood cell counts and haemoglobin estimations were made twice weekly. In the therapeutic cases, sternal bone marrow was examined four or five times during and subsequent to the malarial attack; the bone marrow was examined once only during the attack in the natural infections.

At the commencement of the infection the mean red blood cell count was 4.5 million per cmm. and the mean haemoglobin value 80 per cent. At the end of the infection the mean red count had fallen to 2.7 million and the mean haemoglobin to 60 per cent. The colour index was estimated in 22 cases of *P. vivax* infection. It was equal to or less than 1 in 15 out of 22 cases on the

first day greater than 1 in 19 out of 22 at the end of the malarial attack and equal to or less than one subsequent to treatment. The mean red cell diameter reached a maximum at the height of the infection in the 10 cases of *P vivax* infection examined (7.65 μ compared with 7.3 μ on the first day and 7.35 μ after treatment).

Before infection the reticulocytes in 20 cases varied between 1 and 14 per thousand red cells. During the malarial attack the reticulocytes did not increase in the peripheral blood except in one case in which they reached 25 per thousand red cells. Five days after the commencement of treatment however there was a reticulocyte crisis which in one case reached 175 reticulocytes per thousand red cells. One-third of the cases showed a reticulocyte count of more than 60 per thousand red cells after treatment. Some cases showed a double wave of reticulocytes after treatment a depression in numbers developing with the temporary reappearance of plasmodia in the peripheral blood.

During the malarial attack the bone marrow showed erythropoietic activity with a big increase in reticulocytes which were about eight times as plentiful as in the peripheral blood (the normal ratio of reticulocytes in bone marrow and peripheral blood is given as 3:1). Megaloblasts were seen in two cases only, one of which was the fatal malignant tertian infection.

After cure there was a rapid increase of reticulocytes in the peripheral blood and a corresponding rise in the bone marrow reticulocytes.

In the *P vivax* cases the infection rate of the reticulocytes in the bone marrow was the same as that in the peripheral blood. The stages of plasmodial development seen in the marrow were the same in proportion as those in the peripheral blood except that gametocytes were more common in the latter. There was no evidence of increased damage to the reticulocytes in the bone marrow and the number of plasmodia found in the bone marrow was not greatly in excess of that found in the peripheral blood.

The author considers that the fact that there was no increase in reticulocytes in the peripheral blood during the acute malarial attacks although during this period the reticulocytes increased in the bone marrow indicates that the plasmodia must interfere in some way with the discharge of reticulocytes from the marrow into the peripheral circulation. After disappearance of plasmodia from the blood stream this inhibition ceases.

Anaemia in benign tertian and quartan infections therefore developed mainly from the destruction of red cells by the plasmodia, and was associated with an inhibition of the discharge of young red cells from the marrow.

NOE W L, JR GREENE C C, JR & CHENEY G. The Natural Course of Chronic Southwest Pacific Malaria. *Amer J Med Sci* 1946 Feb 1; 211 No 2: 215-19. 2 charts.

The object of this study was to observe the natural course of relapsing *P vivax* malaria, acquired in the Southwest Pacific, when uninfluenced by specific treatment. It was hoped to ascertain whether or not immunity might develop with sufficient rapidity to justify withholding specific therapy. Seventy-two patients volunteered. 25 of these received no specific treatment of any sort at the Hammond General Hospital where the observations were made. Nineteen received specific treatment at some time during the observations for administrative reasons only. Seventeen had to receive specific treatment for all clinical activity because of the severity of their infections. Two had parasitaemia only. These patients had previously had from 1 to 16 relapses which had been treated the average number being 8.64 for 69 patients. They were under observation for 2 to 10 months.

June, 1946

These patients were thus mostly in the chronic relapsing stage of the infection in which frequent recurrences have become well established—Phase 2 as the authors term it. When specific therapy is withheld Phase 2 is characterized by relapses each of which may include recurrent bouts of chills and fever which tend to assume the single tertian pattern. Each relapse may last from 1 day to more than 3 months. The average duration of 113 untreated attacks was 5-47 days. Between febrile bouts (month temperature 100°F or over) there may be malaise, headache and generalized pains. Parasites are found in the blood during the active periods of this phase. Clinical activity may subside after a single bout of fever or may recur for months. During the final stage of the infection (Phase 3) parasitaemia is constantly or irregularly present but the temperature does not rise above 100°F. An occasional late relapse might occur though none was noted in this series. Phase 3 lasted for 10 to 80 days in 30 cases which were completely followed. It apparently represents the development of immunity and perhaps cure. Phase 2 ordinarily lasts many months and Phase 3 many weeks. "Non-specific therapy is therefore not justified."

The commonly observed cyclic recurrences at regular intervals in chronic South west Pacific malar infections treated with atabrine [mepacrine] are rarely seen if treatment be withheld. Norman White

ANDREW R. A Syndrome in Vivax Malaria probably due to Spontaneous Subcapsular Haemorrhage of the Spleen. *Med. Jl. Australia* 1945 Dec 22, 1, 2 No 25 400-04

Among 6038 patients suffering from *P. vivax* malaria ten developed symptoms strongly suggestive of subcapsular haemorrhage of the spleen. In all the onset of the syndrome was marked by the sudden occurrence of very acute pain in the left upper quadrant of the abdomen. In four cases pain was also severe in the epigastrium and in six, pain was referred to the tip of the scapular process of the left shoulder. There was no trauma. Six patients were lying in bed when pain seized them. One was awakened by pain two hours sitting down and one was in the act of swallowing beer. The pain was accentuated by deep breathing and lasted from a few days to many weeks. In three cases there was tenderness in the left hypochondrium but no true rigidity. A small pleural effusion, signs of pulmonary congestion and complicating pneumococcal pneumonia were all observed. None of the patients was submitted to operation and all recovered.

All the patients had acquired the malaria infection in New Guinea. The syndrome occurred in three cases before treatment had started, in four cases during treatment, in two cases early in the 6 weeks maintenance course of mepacrine and in one case three months after an attack of malaria. Five patients had a history of previous malaria, five had none. There was no fever apart from that caused by still active malaria. The pulse rate was not raised except in the first hour or two of very severe pain. The leucocyte counts were normal.

Only one of three conditions appears at all likely to have been the cause of this syndrome—a small rupture of the spleen, a splenic infarct, or a subcapsular haemorrhage of the spleen. In splenic rupture acute abdominal pain of sudden onset such as characterized these cases, is not common. Moreover it is unlikely that 10 consecutive cases of rupture of the spleen should have recovered without operative treatment. The blood findings in two patients did not suggest that a haemorrhage of any great size had occurred. The diagnosis of splenic infarct is more difficult to exclude. The shoulder pain, and the symptoms

and signs in the pleural sac and the base of the left lung are unlikely however to have been caused by an infarct. Infarcts in the spleen may occur in malaria without causing signs or symptoms. A sudden stretching of the splenic capsule as the result of haemorrhage is the most likely explanation of the sudden abdominal pain and tenderness. The consequent irritation of the diaphragm would explain the shoulder pain and the restriction of normal diaphragmatic movement would account for the changes at the base of the left lung.

LOWE J. Malaria contracted after Splenectomy for Splenomegaly probably caused by Kala-Azar. *Indian Med Gaz* 1945 Nov & 80 No 11 568

Splenectomy was performed on a male patient who was admitted to a Calcutta hospital in 1944 with an enlarged spleen the condition being diagnosed as tropical or Bengal splenomegaly. He recovered uneventfully and was discharged in March 1945. A month later he was readmitted with fever which was diagnosed on clinical grounds as due to kala azar and thus diagnosis was supported by the positive result of a complement fixation test made with WkH antigen and by the response to treatment for kala azar.

In July 1945 he had another attack of fever which lasted for 2 weeks before he came to the School of Tropical Medicine where his blood showed *Plasmodium vivax*. He was admitted to hospital with a temperature of 104.8°F and his liver was enlarged down to the level of the umbilicus. Treatment with mepracrine was effective and he was discharged from hospital a week after admission. The author thinks that the enlargement of his spleen was caused by kala azar which was not diagnosed, that the long duration of malarial fever before treatment was owing to the absence of his spleen and that the great enlargement of his liver during the malarial attack was compensatory for the absence of the spleen. The case indicates that diagnoses of kala azar and malaria should be excluded before splenectomy is done and that persons whose spleens have been removed should treat malaria with more than ordinary respect.

HOWE C. D & DUFF F. L. Effect of Altitude Anoxia in provoking Relapse in Malaria. *Science* 1946 Feb 22 223

In summary neither relapse nor parasitemia was observed in a group of 50 individuals giving histories of recent malaria within a period of 7 days following exposure to the anoxia produced by a 1 hour stay at 18 000 ft. in a low pressure chamber.

LIPPINCOTT S. W. ELLERBROOK L. D. HESSELBROCK W. B. GORDON H. H. GOTTLIEB I. & MARBLE A. Liver Function Tests in Chronic Relapsing Vivax Malaria. *J Clin Investigation* 1945 Sept & 24 No 5 616-22

1 fig [19 refs]

Liver function tests were carried out in a group of 317 patients during and subsequent to attacks of relapsing *P. vivax* malaria treated in most cases by atabrine. The tests used were bromsulphthalein retention after 45 minutes cephalin flocculation galactose tolerance intravenous hippuric acid synthesis determination of icterus index and serum bilirubin serum albumin globulin cholesterol and phosphatase and urinary urobilinogen estimations. Bromsulphthalein was retained 45 minutes after injection in 4 per cent of 49 cases in whom the test was made on the second and third day of the malarial attack. Two to forty four weeks after the attack 3 per cent of 149 patients still showed bromsulphthalein retention.

Cephalin flocculation tests were carried out for the first five consecutive days of the acute attack in 42 patients. The results depended to some extent upon the antigens used (Difco and Wilson) but some abnormal flocculation was found.

Galactose tolerance was normal in 4 to 52 weeks after the attack. Hippuric acid synthesis was tested in 56 men following recurrent malarial attacks, and in 28 normal subjects. The malarial subjects showed some slight depression of synthesis. Icterus index and serum bilirubin were increased slightly during the first days of the malarial attack, but were normal after the attack. Urobilinogen was found in the urine at a dilution of more than 1 in 20 during the early days of the attack but by the fifth day the concentration was within normal limits. The blood proteins were estimated in 172 patients 1 to 28 weeks after an attack in all the albumin content was normal and in three the globulin was raised above 2.7 gm per 100 cc. Only two patients had lowered total protein.

The authors conclude that there is some evidence of transient disturbance of liver function during recurrent attacks. There is little indication of permanent damage.

ROGAN J. M. & COOMBS A. E. R. Some Aspects of Malaria Therapy on the Eastern Frontier of India 1942-44. *Indian Med Gaz.* 1945 Nov v 80 No 11 572-81

In 1942 the authors were deputed to investigate the efficacy of the standard army treatment of malaria among troops in the field in Assam. This standard treatment comprised quinine 30 grains daily for 2 days, mepacrine 0.3 gm daily for 5 days a rest period of 2 days then pamaquin 0.02 gm daily (0.03 gm for British troops) for 5 days.

In an Indian General Hospital in a village in a highly malarious jungle four methods of treatment were compared: the standard method as above; the standard method using Bayer's atabrin and plasmoquine in place of mepacrine and pamaquin; standard treatment modified by continuing the quinine treatment till fever had subsided; standard treatment modified by commencing mepacrine and pamaquin administration. Ninety-two cases were treated by each of these methods each group containing 43 (in 32 *Salicarpurum* and 17 mixed infections). The results showed that the standard treatment was effective for the treatment of the acute stage of uncomplicated cases of malaria occurring under war conditions in Assam. There was no evidence that the malaria encountered in Assam was resistant to treatment. There was no appreciable difference between the response of Indian and British troops to treatment. There was no difference between the results obtained with the synthetic drugs of Bayer's and of British origin respectively. The early relapse rates were moderately high. Repeated reinfections were probably taking place.

In another series of observations in an Indian General Hospital in Gauhati, Assam five methods of treatment were compared: (1) the army standard treatment (2) mepacrine 0.2 gm. every 6 hours for 48 hours then 0.1 gm. thrice daily for 5 days (3) mepacrine 0.2 gm. thrice daily for one day then

0.1 gm thrice daily for 6 days (4) the same treatment as the last followed by pamaquin 0.01 gm. thrice daily for 3 days alkali was given during the mepacrine course to render the urine alkaline before pamaquin was taken (5) initial single dose of 0.8 gm. mepacrine followed by 0.1 gm thrice daily for 7 days Two hundred patients were treated by each method they were all Indians After treatment the patients were sent to a convalescent depot in Shillong which is malaria free for a month's observation

The results showed that all five methods were about equally effective in controlling fever and parasitaemia in the control of fever quinine was slightly more effective than mepacrine in vivax infections but less so in *falciparum* infections Irrespective of the treatment used it took ten days and thirty days from the day of admission for the erythrocytes in vivax malaria to regenerate to the level found on admission and to five million red cells per cmm respectively Corresponding periods for *falciparum* malaria were 25 days and 40 days [Shillong is 4500 ft above sea level blood-counts of healthy residents are likely to be much higher than five million] No abnormality in total or differential leucocyte counts could be attributed to any of the treatments used Vomiting was the most common sign of intolerance this was least common with moderate doses of mepacrine (treatments 3 and 4) and most common in patients treated with an initial dose of 0.8 gm mepacrine (treatment 5) The standard treatment was the least effective in preventing relapse during the observation period With the treatments employing mepacrine only the relapse rate was inversely proportional to the total dosage of mepacrine Pamaquin after a light mepacrine treatment appeared to reduce the relapse rate

As a result of these observations the following recommendations were made that quinine and pamaquin be omitted from the routine treatment which should consist of mepacrine only commencing with a moderately high dosage and that this be followed by suppressive mepacrine treatment

BURNHAM R. C. Acute Atabrine Intoxication Report of a Case. *U.S. Navy Med Bull* 1946 Mar v 46 No 3 434-8. Norman White

A case is described in which acute intoxication by a single dose of more than 90 grains of atabrine resulted in complete recovery without apparent liver damage The patient's suicidal motivation is discussed from the psychiatric viewpoint as representative of a considerable group of suicides.

FITZBUGH O G NELSON A. A. & CALVERY H O with the technical assistance of J M GLASSMAN The Chronic Toxicity of Quinacrine (Atabrine). *J Pharm & Exper Therap* 1945 Nov v 85 No 3 207-21 1 fig & 1 chart. [17 refs.]

Previous experiments by WRIGHT and LILLIE [this *Bulletin* 1944 v 41 99] and by SIEGEL and MUSHETT (*ibid* 1945 v 42 178) showed that quinacrine (atabrine mepacrine) could cause pathological lesions in animals when given in large amounts It was earlier established that the drug accumulates in the tissues. SCUDI and HAMLIN [this *Bulletin* 1944 v 41 728] reported that rats fed on a high protein low fat diet were best able to counteract the toxic effects of the drug When the diet was adequate HEGSTED *et al* [this *Bulletin* 1944 v 41 849] showed that the addition of certain vitamins gave no increased protection The present authors have demonstrated differences in the toxic effects produced by giving quinacrine by mouth to albino rats for practically

For therapeutic purposes the standard course of Paludrine in *P. falciparum* infection was 300 mgm daily for 10 days. With this treatment, radical cure of 12 out of 12 trophozoite-induced and of 64 out of 65 sporozoite-induced, infections resulted. Smaller dosages readily brought about rapid disappearance of trophozoites but the clinical response to treatment was not so rapid. The dosage used in *P. vivax* infection varied from a single dose of 100 mgm. to 1.0 gm. daily for 14 days. The clinical response to treatment was not rapid, and showed little variation with the different dosage schedules. Parasites soon became degenerate but remained in the blood during 5-8 days of therapy the result being dependent to some extent on the amount of drug given and on the original density of parasites. With the maximum dosage of the drug relapses occurred in sporozoite-induced infections after freedom from malaria for 29-88 days but they had not been noted after a considerable period in a few cases treated for overt trophozoite-induced malaria with small doses of drug. The results of treating overt mixed infections were similar to those for the single infections. Of 41 soldiers treated with the standard course of drug for overt *P. falciparum* infection acquired in New Guinea, 12 developed *P. vivax* infections 19-33 days after the last dose of Paludrine but malignant tertian parasites were absent. In two cases of quartan malaria the clinical response was rapid, but parasites disappeared only slowly. It will be seen therefore that Paludrine proved efficient in the clinical cure of the three forms of malaria but that the response was not more rapid than with quinine or mepacrine. The radical cure obtained in *falciparum* infections was according to the authors "in accord with the concept that there are no persistent e.e. forms in *falciparum* malaria, and that radical cure will result from therapy with an efficient schizonticide. It appeared that the number of secondary attacks occurring after treatment of sporozoite-induced *P. vivax* infections with Paludrine was smaller than would have been expected had other known antimalarials been used.

Gametocyte production in *P. falciparum* infections appeared to be unchecked by the standard course of Paludrine. The appearance of these sexual forms in the blood remained unchanged during therapy for a period normally observed when treatment with other non-gametocidal drugs is given. The salivary glands of mosquitoes did not, however become infected and a considerable amount of experimental evidence was obtained regarding the infectivity of gametocytes for mosquitoes after therapy ended. Blood containing gametocytes was then non-infective for mosquitoes for 4-12 days, depending on the dosage which had been given. The drug appeared to exercise its effect on the growth of the parasite in the insect and maturation of the oöcysts present was prevented. The gametocytes of *P. vivax* were unaffected in number or morphology by Paludrine. Either development of oöcysts in the mosquito was prevented or chitinization occurred in those partly developed.

Regarding the mode of action of Paludrine it appeared from a study of the blood parasites in *P. falciparum* infections that the drug affected either the amoeboid forms or a later stage in the schizogonous cycle. This view was confirmed by *in vitro* experiments. It was noted that division of chromatin was arrested, and the asexual cycle thus brought to an end. In studying the action on the (postulated) e.e. forms of this parasite 30 volunteers were given various doses of Paludrine at different times relative to the bites of infected mosquitoes. Some were fully protected, and from others undergoing treatment blood was subinoculated to fresh hosts on the 7th day after exposure with negative results, while those in controls were positive. The evidence available to date indicated that Paludrine in certain doses was a true causal prophylactic and that its action was not on the sporozoite but on a later stage in the cycle of development. These results—considered with others obtained

earlier in which not all cases of overt malaria from sporozoite-induced infections were cured by certain doses of the drug—lead the authors to believe that the e.e. forms are more susceptible to its action than erythrocytic forms. There is other evidence to support this view. Paludrine also has a powerful action on the maturing schizonts of *P. vivax*. In view of the fact that it was in general unable to effect radical cure of this infection produced by mosquitoes indicated that some action took place on sporozoites or e.e. forms whereby the development of the primary wave of parasites was inhibited. In this respect the drug acts as a causal prophylactic but not all e.e. forms are destroyed. In certain circumstances it is believed to act as a complete causal prophylactic.

The toxic symptoms which occurred during therapy were few and not of a serious nature. They were associated generally with maximum dosage of 1.0 gm daily and included vomiting diarrhoea and abdominal pain. Red cells epithelial cells and hyaline casts have been noted in the urine while in one case there was gross haematuria. These symptoms were readily relieved by withholding or reducing the dose of drug which has a wide range of effective action or by clinical cure of the disease. In other cases there was an increase in the myelocytes of the peripheral blood some days after the treatment began possibly as a result of the drug's action on the bone marrow. J. D. Fulton.

MEDICAL J AUSTRALIA 1946 Feb 16 v 1 No 7 234-6 Researches on "Paludrine" (M 4388) in Australia. From the Land Headquarters Medical Research Unit Cairns FAIRLEY N H (Director)] This is an account of the researches recorded in the paper abstracted above in addition a short history of the preceding chemotherapeutic investigations is given.

KNOWLES F L. & FISK F W DDT Water Emulsion in Rice Fields as a Method of controlling Larvae of *Anopheles quadrimaculatus* and other Mosquitoes. *Pub Health Rep* Wash. 1945 Aug 31 v 60 No 35 1005-19 11 figs (2 on 1 pl.)

Flooded rice fields are often habitats for the larvae of anopheline mosquitoes but because of their extent and the susceptibility of growing rice to injury ordinary larvicidal methods are apt to be limited and expensive. The authors have endeavoured to find a safer effective and cheaper method of controlling the breeding of *Anopheles quadrimaculatus* in rice fields by applying a DDT emulsion to the flooding water at the pumping station which supplies the water.

The experiments took place in the Stuttgart area of Arkansas U.S.A. where the flooding water is pumped from deep wells or reservoirs and carried to the fields in canals. The experimental fields were of two sizes six plots of 12-18 acres each and 30 plots of 1/20th of an acre each. Different kinds of rice were sown in different plots but the method of culture was the same in all.

To determine the prevalence of mosquito larvae a sampling routine was established both in the treated and in the untreated fields. In the six large plots the sampling stations were at varying distances from the water entrance. In the small plots two sampling stations were located one at each end. Fifteen negative dips were regarded as sufficient 20 dips were taken if larvae were scarce and never less than ten if larvae were numerous. After a few days sampling was done weekly. Larvae of the rice field mosquitoes (*Psorophora ferox* and *P. discolor*) were common at the beginning of the season and

also after the first flooding but later larvae of *Anopheles quadrimaculatus* were most abundant. Larvae of *Culex erraticus* were also present.

The larvicide consisted of DDT (1 part) a solvent (3 parts) and Triton X 100 (1 part). The solvents were xylol, Culicide B oil, Dendrol or xylol plus Culicide B oil. A description is given (and a diagram) of the apparatus for dispensing the larvicide on the large plots at the rate of 0.1 p.p.m. in the flooding waters at the pump. The delivery rate was checked and recorded every half hour at the outlet. To the small plots DDT was applied individually in concentrations ranging from 100 to 0.1 p.p.m.

Data obtained from 28 000 larval counts are discussed and analysed in nine tables, comparing DDT dosage, solvent, type of plot, distance from water inlet and the counts made in untreated ricefields. The larval counts in the large plots irrespective of the treatment or the dosages increased with the distance from the water inlet, thus indicating a loss of toxicity as the water flowed through the canals. Generally speaking treated fields contained 50 per cent. fewer *Anopheles quadrimaculatus* larvae and 72 per cent. fewer culicine larvae than untreated fields, although the fish *Gambusia* was present in the untreated but not in the treated fields. In the small plots, both anophelines and culicines were completely controlled by DDT concentrations of 1.0 p.p.m. and 0.2 p.p.m., respectively. There was no residual toxicity after one application.

The authors conclude that the addition of DDT to the flooding waters as it enters the ricefields will reduce the breeding of mosquitoes but will not eradicate them. It is considered that the rice suffered no injury from the DDT treatments indeed, there was an increase in the rice yield, perhaps as a result of the toxic effect of DDT on the rice water weevil [*Lissorhoptrus simplex*] though this may not be the sole reason.

H S Lesson.

JONES H. A. DEONTER, C. C. BURWELL, R. W. & KNIPPLING E. F. Larvicidal Aerosols containing DDT. *J. Econom. Entom.* 1945 Aug. v. 38 No. 4 432-3.

A mist or aerosol of DDT prepared by the emission of a DDT in methyl chloride solution from an aerosol cylinder is lethal to anopheline larvae up to a distance of 60 ft. from the place of emission. Tests were carried out in a very large room in which pans of water were exposed to varying aerosol doses of DDT. Larvae of *Anopheles quadrimaculatus* subsequently placed in pans exposed at 20, 30, 40 and 60 ft. were killed, and it was shown by the subsequent addition of live larvae that the pans at 20 and 30 ft. distance received a sufficient dose of DDT to remain toxic to larvae despite repeated artificial rain, for a period of 27 days.

Field tests confirmed that the method could be of practical value and full control was achieved with a dosage of 0.1 lb. per acre on swamps of up to 750 sq. ft.

WISECUP C. B., BURWELL, R. W. & DEONTER, C. C. DDT Sprays Mechanically Dispersed for Control of Anopheline Mosquito Larvae. *J. Econom. Entom.* 1945 Aug. v. 38, No. 4 434-6.

A difficulty in the use of DDT as an anopheline larvicide is that the required dose of oil solutions is so small that their regular and even distribution presents technical difficulties. Aerosol bombs have been shown to be a convenient means of distribution, and in the work recorded in this paper the authors tried distribution in the aerosol form with hand atomizers, power sprayers, a large chemical sprayer of the Flit-gun type, knapsack sprayers and the "decontamination type of spray cylinder". The last two were the most efficient for

the treatment of large rather inaccessible breeding areas they are presumably pneumatic sprayers from which the fluid is ejected by direct air pressure on its surface and is mechanically scattered by a nozzle stated to be of 56 to 60 gauge orifice and a whirl plate

By this means it proved possible to treat very large areas. For instance in one breeding place 287 100 sq ft in extent full control was achieved up to 500 ft. from the point of application but the results depended very greatly on the wind—variable gusty or strong winds interfered with the even deposition of DDT. In consequence the method is reliable only in the hands of well-trained and observant operators. The authors conclude that distribution in must form should be of especial value where potholes hoof prints wheel ruts and other small depressions provide scattered breeding places or in breeding areas that are difficult to treat because of depth of water.

[As an anopheline larvicide DDT will not be used to its full value until means of distribution are devised which take full advantage of the minute doses needed. Both distribution in mists and distribution by discrete application of small doses from an oil-can as described by RIBBANDS (this *Bulletin* 1946 v 43 409) appear to have definite advantages over more conventional methods and each will probably have its own sphere of utility. The reviewer hopes that other workers will specify more exactly the type of apparatus used as colloquial descriptions and trade names are not generally comprehensible.]

G Macdonald

ANDERSON B G The Toxicity of DDT to *Daphnia*. *Science* 1945 Nov 23 539

This is a note to the effect that DDT in concentrations of 1 to 100 parts per billion [thousand million] of water immobilizes *Daphnia magna*. Less than 1 part per billion is ineffective. These results may be important in relation to the use of DDT for mosquito control since in many localities it is essential that the zooplankton be protected.

Charles Wilcocks

DEONIER C C & JONES H A TDE, 1,1-Dichloro-2,2-bis (p-Chlorophenyl) Ethane, as an Anopheline Larvicide. *Science* 1946 Jan. 4 13-14

The compound TDE (which differs from DDT in having only two chlorine atoms on the ethane nucleus instead of three) was tested for toxicity to larvae of *Anopheles quadrimaculatus*. The tests were made by comparing TDE and DDT in (i) acetone suspensions (ii) impregnated talc dusts and (iii) fuel-oil solutions which were atomized and allowed to settle on the water containing the larvae.

In all tests the TDE appeared to be very slightly more toxic than DDT (except that the "knock-down" with a 0.01 p.p.m. acetone suspension was rather quicker with DDT than with TDE).

BLACKWATER FEVER.

YULE C L, GOLD M A & HINDS E. G Hemoglobin Precipitation in Renal Tubules. A Study of its Causes and Effects. *J Exper Med* 1945 Nov 1 v 82, No 5 361-74 3 text figs & 4 figs on 1 pl. [22 refs.]

The authors review the literature on the question of the genesis of the syndrome of renal failure associated with intravascular haemolysis. They point out that such syndromes all have in common the circulating pigment

a factor " of vascular or chemical nature affecting the organism as a whole and a specific kidney lesion with varying degrees of tubular degeneration and obstruction of tubules by pigmented casts in the convoluted and collecting tubules and ascending loops of Henle.

The theories concerning the cause of the kidney changes in the syndrome are briefly discussed.

The authors investigated the problem by injecting solutions of haemoglobin into rabbits which were secreting acid or alkaline urine and in which the kidney tubules were damaged either by temporary clamping of the renal artery [see SCARFF and KEELE *Bulletin of War Medicine* 1944 v 4 370] or by the previous poisoning of a specific poison in this case sodium tartrate.

White domestic rabbits were used and given a diet of rabbit chow and vegetables (for the production of alkaline urine) or oats and stale bread (for the production of acid urine). Water was allowed freely with both diets. The haemoglobin solution was obtained from citrated rabbit's blood. The doses of haemoglobin injected were the equivalents of the amount set free by the lysis of the cells in 200 to 400 cc. human blood. Selective tubular damage was obtained by clamping the renal artery (in previously unilaterally nephrectomized animals) for 15 or 25 minutes or by the subcutaneous injection of 20 per cent. sodium tartrate in doses of 0.8 to 0.95 gm. per kilo.

Preliminary experiments showed that the injection of the haemoglobin solution into normal animals was not followed by evidence of renal dysfunction whether the urine was acid (two animals) or alkaline (two animals).

Following the clamping of the renal pedicle for 15 minutes (the haemoglobin solution was injected 5 minutes before the release of the pedicle) haemoglobin casts were found in the animals with acid urine but were "not so numerous" in the animals with alkaline urine. In two animals with acid urine there was a pronounced rise of blood urea N after the injection of haemoglobin one animal developed temporary oliguria.

When the renal artery was clamped for 25 minutes there was a transitory rise in blood non-protein nitrogen [N P N] which returned to normal in 7 days with short periods of oliguria and anuria. In the animals with alkaline urine the rise of blood N P N was more persistent and there was transient oliguria. In two animals with acid urine there was a sharp rise in N P N following haemoglobin injection, and both became anuric. Both died on the fifth day and there were haemoglobin casts in the tubules in both. A third animal with acid urine showed a rise in N.P.N. without accompanying change in urine volume. This animal was killed on the eighth day and was found to have many haemoglobin casts in the tubules the renal pedicle had been clamped a month previously and there was some scarring of the pedicle. The authors suggest that the result obtained may have been due to failure to occlude lateral circulation through the scar tissue.

In the tartrate experiments the degree of renal damage was maximal in the animals secreting acid urine. Haemoglobin casts appeared in both groups of animals after injection of haemoglobin they were more numerous in the animals passing acid urine. Blood N P N rose moderately after tartrate injection in both "acid" and "alkaline" animals. There were only minor changes in urinary volume. In the animals injected with haemoglobin subsequent to injection of tartrate a rise of N.P.N. (above that already produced by the tartrate injection) occurred in one (of 4) "alkaline" animals and two (of 4) "acid" animals. Urinary volume was unchanged in one "alkaline" animal, is not stated in another and was reduced in two one animal going into intermittent anuria. The alkaline animal showing a rise of N.P.N. died on the fifteenth day there were no tubular casts but there was a high degree of tubular necrosis and some calcification. Urinary volume was reduced in

two of the acid animals and in two it is not stated. One animal died in oliguria the other was killed on the twelfth day. There were many haemoglobin casts in the former and occasional casts in the latter.

The authors conclude from their experimental results that the precipitation of haemoglobin in the renal tubules is not primarily dependent on the reaction of the urine but on functional abnormality of individual nephrons indicated histologically by lesions of the tubules. These alterations in the tubules are non-specific since they can be produced by either ischaemia or chemical poisoning (tartrate).

Given the combination of renal tubular damage and haemoglobinuria urinary pH may be important since pigmented (haemoglobin) casts are more common in animals secreting acid urine than in those secreting alkaline urine.

B G Macgregor

BUTTS D. C. A. The Rh Factor in Blackwater Fever. A Preliminary Note
Amer J Trop Med 1945 Sept v 25 No 5 417-20 [30 refs.]

In this preliminary note the author suggests that a factor concerned in the development of blackwater fever may be isoimmunization to an Rh like substance present in malarial plasmodia. According to WIENER (quoted as a personal communication) isoimmunization to the Rh factor occurs in 2-4 per cent. of Rh negative individuals following transfusion with Rh positive blood or the birth of an Rh-positive foetus. From this the author calculates the possible incidence of blackwater fever per 1 000 using LEVINE's figures for the incidence of the Rh factor in whites, negroes and Chinese. He compares his calculated results with figures recorded by various authors for the incidence of blackwater fever and erythroblastosis foetalis in whites and negroes. The following table (from the text) summarizes findings —

	Ratios	
	White	Negroes
(a) Cases of blackwater fever (calculated)	30 to 60	9 to 18
(b) Cases of blackwater fever (Deeks and James, 1911)	33 to 59	2.5 to 5.9
(c) Deaths from erythroblastosis foetalis	37	2

The figures in the table are misleading. The ratios in line a of the table are based on figures giving the incidence of blackwater fever per 10 000 cases of malaria; those in line b are based on figures giving the incidence of blackwater fever per 10 000 of the racial population. The two sets of figures are therefore not comparable. The author may be excused this error on the grounds of the incredible obscurity of both text and tables in the report by Deeks and James (DEEKS W. E. and JAMES D. M. *Report on Haemoglobinuric Fever in the Canal Zone* I.C.C. Press 1911 32) but his figures in line c of the table can be due only to bad arithmetic: the real proportion calculated on the basis of deaths from erythroblastosis foetalis per 10 000 foetal deaths is nearer 3 to 1 than his figures of 37 to 2 [see POTTER *Bulletin of Hygiene* 1941 v 16 59]. The rest of the paper deals shortly with aspects of multiple cases of blackwater fever in the same family, stillbirths and blackwater fever and the rôle of antimalarial drugs in blackwater fever.

B G Macgregor

PETERS J T Origin and Development of a New Therapy for Crush Injury Transfusion Kidney and a certain Number of other Diseases. *Acta Med Scandinavica* 1945 v 123 No 1 90-100 5 figs.

The author states that after an autopsy on a woman who had died of mercuric chloride poisoning he decided to search for "a satisfactory explanation as to how the tubular epithelial cells with almost undamaged glomeruli could produce anuria. Just the reverse would have been expected with such a destruction of the elements of reabsorption." An artificial nephron was constructed and experiments with this suggested that increased intrarenal pressure was an important factor in producing oliguria and anuria.

The author lists 32 diseases including blackwater fever in which oliguria or anuria accompanied by uraemic symptoms may occur. He advises decapsulation of the kidneys as an emergency operation in such conditions.

[The paper is diffuse and unconvincing. The author quotes from a letter from the Editor of the *Lancet* stating that "The treatments which you recommend—decapsulation, diuretics and pressor drugs—are now widely used, separately or in combination." B G Macgregor.]

TRYPANOSOMIASIS.

RIDLEY H. Ocular Lesions in Trypanosomiasis. *Ann Trop Med & Parasit* 1945 Oct. 10 v 39 No. 2, 66-82. [51 refs.]

During the years 1943-44 ophthalmic examinations were performed by the author on 215 West African patients suffering from trypanosomiasis. These patients comprised 39 African soldiers, 44 African civilians (a high proportion of whom were selected on account of past or present eye complaints and whose attendance for ophthalmic examination was arranged) and 132 other African civilians entirely unselected, who happened at the time to be attending trypanosomiasis dispensaries. Of these 215 patients 64 were found to have ophthalmic complaints and 32 of these had lesions of the retina and visual pathway caused by the toxic effects of therapeutic arsenic. Of the remaining 32 who had inflammatory changes in the structure of the eyes, in 10 they were attributable to onchocerciasis, in 14 to miscellaneous injuries and infections and in only 8 they were regarded as directly due to trypanosomiasis. These eight comprised one patient with nystagmus parkinsonism, with severe mental derangement; two who showed bilateral papilloedema of moderate degree which was observed to subside during treatment; four in whom the indefinite disk edges and the presence of new connective tissue in the physiological cups and around the central retinal vessels suggested that a similar condition had at one time been present; and only one in whom otherwise unexplained keratitis was found. The keratitis was interstitial and whether or not it was directly due to trypanosomiasis remains in doubt, for it was not possible to examine the eye microscopically for the parasite. The cases with swollen optic disks are confidently reported as papilloedema and not as papillitis because there was little or no visual impairment even in the acute stage and because no degree of pallor followed resolution of the swelling. It is possible that the secondary optic atrophy and narrowed retinal vessels reported by observers who had the opportunity of examining the fundus oculi in a large number of untreated patients may in some instances have resulted from chronic papilloedema. Other cases may be due to onchocerciasis.

The supreme importance of onchocerciasis as a cause of ocular inflammations including keratitis iridocyclitis choroidoretinitis and optic atrophy in trypanosomiasis patients is demonstrated by this investigation and the author has been able when visiting trypanosomiasis clinics in the Gold Coast to find unsuspected cases of ocular onchocerciasis and to confirm the diagnosis by the demonstration of intraocular microfilariae. Onchocerciasis is without doubt the predominant cause of ocular inflammations in trypanosomiasis subjects.

The miscellaneous lesions require little comment being such as might occur in any series of inhabitants of the African bush.

The following conclusions are drawn from the author's observations —

1 In man inflammations due to the presence of trypanosomes within the tissues of the eye are rare and as yet no case has been proved by microscopical examination. The substantia propria of the cornea is the part most likely to be affected.

2 Such inflammations are practically confined to the terminal stages of the disease shortly preceding death. Intraocular trypanosome infection cannot be regarded as a common or important cause of impaired sight in Africa.

3 Ocular abnormalities are found in uncomplicated trypanosomiasis but these are secondary to infection of the meninges and central nervous system and resemble those found in other forms of lymphocytic meningo-encephalitis. The commonest of these is papilloedema which may develop in the acute stage of infections of only moderate severity. More rarely ophthalmoplegias, Argyll Robertson pupils and nystagmus occur.

4 Concurrent onchocerciasis is common and ophthalmologically important. This disease in all probability accounts for the majority of cases of intraocular infections, keratitis, iridocyclitis, choroidoretinitis and very possibly optic atrophy when occurring in untreated cases previously attributed to trypanosomiasis.

5 The risk of amblyopia and even amaurosis from therapeutic arsenic is serious.

NELSON J W The Treatment of Rhodesian Trypanosomiasis with Penicillin.
East African Med J 1945 Dec v 22 No 12, 407-8

The patient was a man in an advanced stage of Rhodesian sleeping sickness unlikely to live for more than a few weeks if no treatment were given while treatment with the usual drugs would have been useless. penicillin was therefore tried.

He was in a stuporose state unable to answer questions and incontinent. the superficial lymph glands were not enlarged. very slight oedema of the legs was present. Trypanosomes were numerous in the blood and cerebrospinal fluid and the latter showed 0.1 per cent. of protein and 568 cells per cmm. 96 per cent being lymphocytes. Other blood findings were erythrocytes 5 360 000, haemoglobin 12.6 gm (90 per cent Sahli), formal gel +10 minutes opacity ++, serum proteins 8.8 gm — albumin 3.4 gm, globulin 5.4 gm. Kahn reaction negative. E.S.R. 97 mm in 1 hour 117 mm in 2 hours.

He was treated with penicillin as follows: 20 000 units i.m. every 3 hours for 7 days; 40 000 units i.v. on the first day; 20 000 units intrathecally on the 2nd and 6th days. total, 1 250 000 units in 8 days.

Trypanosomes were found in the cerebrospinal fluid on the 2nd day [of treatment ?] but not on the 6th day nor after death which occurred on the 16th day after admission. they were present in the blood throughout. After death the cerebrospinal fluid contained 0.5 to 1 unit of penicillin per cc.

LOWE J. Kala Azar [Correspondence.] *Trans Roy Soc. Trop Med & Hyg* 1946 Feb v 39 No 4 345-6.

In a recent paper by SHOKT [this *Bulletin* 1946 v 43 317] Lowe is quoted as saying that urea-stibamine is as effective as any of the new preparations the author explains that this drug is cheap fairly safe and effective and is therefore suitable for the treatment of outpatients in India, but has the disadvantage that it must be given intravenously. Some other preparations may be slightly more effective e.g. neostibosan which is not cheap and has not been available for some years diamidino-stilbene which is unsuitable because it produces toxic reactions and "solustibosan" (sodium antimony gluconate) the value of which, however cannot yet be estimated. "Aminostiburea" is apparently identical with urea-stibamine and is even cheaper while stibatin (Glaxo) appears to be the same as solustibosan.

The author prefers sternal puncture to splenic puncture and reserves the latter for old-standing cases in which sternal puncture has given negative results.

HALAWANY A. & JALILI M. Investigation into the Effect of Penicillin on *Leishmania Tropica* *J Roy Egyptian Med Ass.* 1945 Aug v 28 No. 8, 394-6.

"1. Sodium penicillin in a concentration of 1000 units does not possess any effect on leptomastix forms of *Leishmania tropica* in culture.

2. The application of dressings soaked in an aqueous solution of sodium penicillin possessing a strength of 20 Oxford units to each c.c. of distilled water or normal saline cures the secondary infection but has no effect on the lesion itself. The same can be said of the application of ointment containing 200 units of sodium penicillin in each gram of vaseline.

FEVERS OF THE TYPHUS GROUP

FITZPATRICK Florence K. Studies on Cultivation of Rickettsiae in Eggs. *J Lab & Clin Med* 1946, Jan., v 31 No. 1 45-55 [37 refs.]

This paper contains a number of useful technical hints in connexion with the cultivation of rickettsiae in yolk sacs. It should be read by all who are engaged in this work. Only a few examples are given in this summary.

The rickettsial strains employed were the Breinl epidemic, the "Wilmington immune, and two of "spotted fever" (Rocky Mountain spotted fever).

Eggs from pullorum tested flocks of white Leghorn hens were used. In most cases they were inoculated at the 7-day incubation period. Smears were stained by a modification of the Macchiavello method in which the basic fuchsin was diluted with sterile distilled water which had not been neutralized. Methylene blue was used in staining smears for testing sterility. The fragments of yolk sac used for making smears were taken from the point of attachment to the embryo.

Chick embryos of the 8th or 9th days were found most suitable for inoculation with "spotted fever" rickettsiae. Incubation at 34-35°C. gave the best results with all strains.

With epidemic and spotted fever strains chick embryos were more susceptible than guinea-pigs to minimum doses of infection. With endemic strains little difference in susceptibility was observed. Contrary to what happens with viruses the addition of immune serum to the rickettsial inoculum did not delay the death of the chick embryos.

No antigen was detected in the yolk substance so long as the embryos were still alive but several hours after death the yolk contained soluble antigen, derived, presumably from autolysis of the yolk sacs. For experimental study of the antigens it was found better to omit ether treatment of the suspensions and to add 1.0 per cent. formalin instead of 0.1 per cent. the stronger formalin apparently delays the disintegration of the rickettsiae

ZARAFONETIS C J Serologic Studies in Typhus-Vaccinated Individuals. I. The Effect of a Stimulating Dose of Typhus Vaccine on the Weil-Felix and Complement-fixing Antibodies. *J Immunology* 1945 Nov v 51 No 5 365-74 [11 refs.]

John W D Megaw

The author working with the U.S.A. Typhus Commission in Cairo studied the Weil-Felix and complement fixation responses in 100 persons who had previously received standard courses of Cox type epidemic typhus vaccine and in nearly every case two to five later stimulating doses of the vaccine at three monthly intervals. In every case the last of the stimulating doses had been given at least three months before the first test was carried out. All the sera were tested and immediately a further stimulating dose was given to each person. Later tests were made at intervals of two and eight weeks. The Weil-Felix titre (OX19) was 1-40 to 1-80 in 17 cases just before the stimulating dose, two weeks later these titres were reached in 21 cases so that the changes in the reaction were insignificant. The reaction with OX2 was negative in every case and only one person gave a positive reaction (1-160) with OAK the titre being the same before and after the stimulating dose. No explanation could be found for this reaction.

In the complement fixation tests both epidemic and murine antigens were used. Before the final stimulating injection 21 persons were positive with epidemic antigen and seven of these were also positive with murine antigen. Two weeks after the injection 70 persons were positive with epidemic antigen and 34 of these were also positive with murine antigen but usually at considerably lower titres. The findings in 27 cases are shown in a table from which the following analysis has been prepared by the reviewer —

Complement Fixation Reactions

Titres observed	Epidemic Antigen			Murine Antigen		
	Before injection	After 2 weeks	After 8 weeks	Before injection	After 2 weeks	After* 8 weeks
Negative	18	0	13	24	8	17
1-4 to 1-8	7	4	9	3	15	9
1-16 to 1-32	2	19	5	0	4	0
1-64 to 1-128	0	4	0	0	0	0

*In one case no test was made

From the original table it appears that two weeks after the injection seven persons had titres half as high (1-4 to 1-16) as their epidemic titres (1-8 to 1-32) and eight weeks after the injection two who gave negative epidemic reactions were positive (1-4) with murine antigen one other gave the same titre with both antigens and two had a murine titre half as high as the epidemic titre

LOWE J. Kala-Azar [Correspondence.] *Trans Roy Soc Trop Med & Hyg* 1946 Feb. v 39 No 4 345-6.

ZARAFONETIS C. J. Serologic Studies in Typhus-Vaccinated Individuals. I. The Effect of a Stimulating Dose of Typhus Vaccine on the Weil-Felix and Complement-fixing Antibodies. *J. Immunology* 1945 Nov 51 No 5 365-74 [11 refs.]

The author working with the U.S.A. Typhus Commission in Cairo studied the Weil-Felix and complement fixation responses in 100 persons who had previously received standard courses of Cox type epidemic typhus vaccine and in nearly every case two to five later stimulating doses of the vaccine at three-monthly intervals. In every case the last of the stimulating doses had been given at least three months before the first test was carried out. All the sera were tested and immediately a further stimulating dose was given to each person. Later tests were made at intervals of two and eight weeks.

The Weil-Felix titre (O\19) was 1-40 to 1-80 in 17 cases just before the stimulating dose. Two weeks later these titres were reached in 21 cases so that the changes in the reaction were insignificant. The reaction with OX2 was negative in every case and only one person gave a positive reaction (1-160) with OAA the titre being the same before and after the stimulating dose. no explanation could be found for this reaction.

In the complement fixation tests both epidemic and murine antigens were used. Before the final stimulating injection 21 persons were positive with epidemic antigen and seven of these were also positive with murine antigen. Two weeks after the injection 70 persons were positive with epidemic antigen and 34 of these were also positive with murine antigen but usually at considerably lower titres. The findings in 27 cases are shown in a table from which the following analysis has been prepared by the reviewer —

Complement Fixation Reactions

Titres observed	Epidemic Antigen			Murine Antigen		
	Before injection	After 2 weeks	After 8 weeks	Before injection	After 2 weeks	After* 8 weeks
Negative	18	0	13	24	8	17
1-4 to 1-8	7	4	9	3	15	9
1-16 to 1-32	2	19	5	0	4	0
1-64 to 1-128	0	4	0	0	0	0

*In one case no test was made

From the original table it appears that two weeks after the injection seven persons had titres half as high (1-4 to 1-16) as their epidemic titres (1-8 to 1-32) and eight weeks after the injection two who gave negative epidemic reactions were positive (1-4) with murine antigen one other gave the same titre with both antigens and two had a murine titre half as high as the epidemic titre

The complement fixation titres showed a pronounced tendency to return to the pre-injection level within eight weeks of the stimulating dose and the degree of cross-fixation with purified murine antigen "was greater than anticipated"

[The cross-fixation referred to is of interest in connexion with the problem of the relationship between epidemic and murine rickettsiae. Anomalous responses in "endemic-typhus" patients who had previously been inoculated with epidemic vaccine have also been reported by PLOTZ and WERTMAN this *Bulletin* 1946 v 43 429] and the degree of cross-fixation observed by the author was much greater than that found by BRINTON [below] for different strains of *Rickettsia orientalis*—its occurrence may be regarded as favouring the view that *R. prowazeki* and *R. mooseri* are variants of the same species of rickettsiae rather than distinct species.

Further investigations will doubtless throw light on these and other puzzling findings obtained in the complement-fixation test as applied to the fevers of the typhus group]

John W D Meager

ZARAFONETIS C J Serologic Studies in Typhus-Vaccinated Individuals. II. The Effect of Non-Typhus Fevers on the Well-Felix and Complement-fixing Antibodies. *J Immunology* 1945 Dec. v 51 No. 6 375-88.

In this paper the author provides a reply to the important question—Are typhus-vaccinated persons likely to give rising titre reactions with the Well-Felix and complement-fixation tests in attacks of fevers other than typhus? For all practical purposes the answer is—no!

The present study deals with tests of sera from 104 vaccinated persons suffering from such febrile illnesses as nasopharyngeal catarrh, lobar pneumonia, febricula, atypical pneumonia and malaria. The amount of vaccine received prior to the illness ranged from three to eight ml. Among the patients 12 gave positive Well-Felix reactions at titres ranging from 1-40 to 1-160 with *Proteus* OX19 and two reacted at 1-40 to 1-80 with *Py* OX2. The titres in every case remained constant throughout the illness and no positive reactions appeared among patients who were initially negative.

The complement-fixation reaction with epidemic typhus antigen was positive 1-4 to 1-256 in 55 of the patients—the usual titres were 1-4 to 1-16. Those who gave positive reactions were tested also with murine antigen and 29 reacted at titres of 1-4 to 1-128. Usually the epidemic titre was twice to four times as high as the murine but in seven cases the same low titre of 1-4 was observed with both antigens. This relatively slight difference between the epidemic and murine titres corresponded with the results observed by the author in his earlier study of the reaction in vaccinated persons [see abstract above].

The titre rose during the febrile attack in eight cases but in seven of these the rise was either from 0 to 1-4 or a doubling of the earliest observed titre and in the one case in which the rise was from 0 to 1-8 the patient had received a booster dose of vaccine two days before the onset of the fever. There was therefore no evidence of the occurrence of rises in the titre such as occur in attacks of typhus fever.

The high proportion of positive complement fixation reactions observed in this group is largely explained by the considerable number of the persons who had received booster doses of vaccine within the previous two months.

The author points out that with the complement fixation test a titre as low as 1-4 can be accepted as indicating a positive reaction because no instances of non-specific reactions in properly controlled tests have been reported up to the present time.

RUBIN S S An Allergic Reaction following Typhus-Fever Vaccine and Yellow-Fever Vaccine due to Egg Yolk Sensitivity *J Allergy* 1946 Jan. v 17 No 1 21-3

MOOSER H & LÖFFLER, W Ein Fall sogenannter Brill'scher Krankheit in Zurich. Ein Beitrag zur Hypothese der späten Rückfälle beim klassischen Fleckfieber [A Case of the So-Called Brill's Disease in Zurich.] *Schweiz med Woch* 1946 Feb 23 v 76 No 8 150-53 1 fig [17 refs]

The authors describe a very interesting case of epidemic typhus fever. The patient was an Armenian carpet worker aged 52 years. He gave a clear history of having suffered from a severe attack of typhus fever in South Russia in 1918. Since his arrival in Switzerland in 1939 he had never been in contact with a known or suspected case of typhus fever and he had never been infested with lice. The authors state that apart from a few cases of laboratory infection and some isolated cases among refugees who had arrived from Germany during the incubation period there had been no typhus fever in Switzerland since 1940. The possibility of infection through handling infected articles in the course of the patient's occupation was excluded because imports of all such goods from the east had ceased for several years.

The attack occurred in June 1945. It was moderately severe and lasted 14 days. The rash was pronounced, it extended to the palms and soles and became haemorrhagic.

The Weil-Felix reaction was negative on the 12th day but was positive 1-640 on the 19th day when the complement fixation test was also positive at a titre of 1-1,280 with epidemic typhus antigen and at a titre of 1-320 with murine-typhus antigen.

The authors conclude that the case strengthens the hypothesis of ZINSSER that infection may persist for many years in the body after an attack of typhus fever and may cause a greatly delayed relapse. This conclusion seems to suggest that the authors incline to the view that infection can be carried over between epidemics by persons who harbour latent infection of this kind but they emphasize the fact that nothing is known with certainty as to the manner in which infection persists during the inter-epidemic periods. They discuss the other theories dealing with the carry-over of infection and dismiss the view that inapparent infections are responsible. They consider that the dried-house-faeces theory is based on the unreliable evidence of what happens in purely artificial conditions. Even the theory of maintenance of infection in rat fleas in the form of murine rickettsiae is admitted to be purely speculative so long as there is no experimental evidence that *Rickettsia mooseri* can undergo transformation into *R. prowazeki*.

No mention is made of an attempt to isolate the rickettsia from the present patient. The complement fixation test is accepted as supplying proof that *R. prowazeki* was the causal agent.

John W D Megaw

BERGER E. & BRZEZINSKI S Chemotherapie der Fleckfieber-rickettsien-intoxikation und ihre Aufhebung durch p-Aminobenzoesäure. [The Chemotherapy of Typhus-Rickettsia Intoxication, and the Inhibitory Effect of p-Aminobenzoic Acid (on the Antidotal Action of Sulphonamides)] *Schweiz med Woch* 1946 Mar 2 v 76 No 9 173-4 [17 refs]

The authors have already shown that the toxic effect produced in white mice by the intraperitoneal injection of lung substance heavily infected with typhus rickettsiae can be greatly diminished by subcutaneous injections of 2 mgm. of sodium sulphathiazole or Na N-3 4-dimethylbenzoylsulphanilamide ("Irgafen"). No significant antimicrobial action was observed.

They now show that *p*-aminobenzoic acid inhibits the antitoxic action of the sulphonamides.

All the mice used in the experiments received similar heavy doses of highly toxic rickettsial suspensions prepared from the pneumonic lungs of infected mice and injected into the peritoneal cavity. The control mice in each set of experiments received these doses and were not otherwise interfered with in any way.

In the first series of experiments three lots of mice were given the standard doses of toxic material, but sodium sulphathiazole had been added 40 minutes before these were administered. All of 10 mice inoculated with this material survived for 48 hours and also all of 10 mice to which 1.0 mgm. of *p*-aminobenzoic acid had been given subcutaneously in addition. But the third lot of mice to which larger doses of 10 mgm. of *p*-aminobenzoic acid were given, had 7 deaths among 10 animals within 24 hours.

There were 15 deaths among 20 control animals within 48 hours.

In the second series of experiments a course of subcutaneous injections of Irgafen was started 2½ hours before the injection of the toxic material. Five doses of 2 mgm. each were given over a period of 24 hours. Among 12 mice treated in this way there were 3 deaths all within 18 hours. In another lot of 12 mice treated in the same way but with the addition of five doses of 2 mgm. each of *p*-aminobenzoic acid, given subcutaneously within five minutes of the doses of "Irgafen," there were 10 deaths within 48 hours.

Of 20 control mice 19 died within 48 hours.

In the third series of experiments *p*-aminobenzoic acid was given by the mouth, in 5 doses of 3 mgm. each to 11 mice to which the toxic injection was given one hour after starting the same course of Irgafen as was employed in the second set of experiments. 10 of these mice died within 48 hours as compared with 5 deaths among 12 mice to which Irgafen had been given but to which no *p*-aminobenzoic acid was administered.

Of 20 control mice in this series 18 died within 48 hours.

The authors conclude from these findings that *p*-aminobenzoic acid abolishes the antidotal action of sulphonamides on the rickettsial toxins.

They also discuss the theory that the action of the sulphonamides is on the metabolism of pathogenic organisms and conclude from their own and other workers' observations that this theory is based on inadequate evidence, and therefore cannot at present be accepted as a working hypothesis in experimental chemotherapy.

CAVAILLOX A. BERNARD L., BOYER & DELECOURT. La lutte contre le typhus exanthématique en France après la libération. [The Campaign against Exanthematic Typhus in France after the Liberation.] *Bull Acad UAI* 1945 v 129 Nos. 36, 37 & 38 637-72, 1 fig.

The authors state that typhus fever did not occur in the expected widespread epidemics after the return of about two million persons from Germany in 1945 and explain why this was so.

The first alert was in February when 97 cases occurred among 2,500 Russian soldiers in a camp at Courme. This epidemic was promptly controlled. A comprehensive plan of action was prepared at a conference of the Ministries, of War, Public Health and "P.D.R." A sanitary barrier was set up on the left bank of the Rhine from Switzerland to the North Sea and provision was made for the inspection and disinfection of every person who crossed the river from the East. Before this had been organized a number of persons had returned to France within the incubation period, so that steps were taken to

ensure the notification and segregation of everyone who had a suspicious febrile attack within 15 days of returning to his home.

The number of cases verified in April 1945 was 31 in May it rose to 229 in June it fell to 51 and in July to 5 In August September and October no cases were reported.

The regional public health centres throughout France were supplied with 250 tons of DDT powder [strength not specified]

The Departments specially affected were the Seine (183 cases mostly in Paris) the Bas-Rhin (20) the Rhône (16) and the Nord (15) Paris was the main clearing centre to which most of the repatriated converged before returning to their homes

Three-fourths of the patients were political deportees 50 of these came from Buchenwald 22 from Mauthausen 10 from Neuengamme 9 from Dachau and the rest from 14 other camps.

The success of the campaign was attributed chiefly to dusting with DDT which was carried out in Germany on the Rhine in the Frontier Reception Posts in Paris and in the Provinces. The percentage of louse infestation among the patients in the Paris hospitals fell rapidly from 44 in the middle of April to about 13 in the middle of May Only 21 secondary cases were detected. Making the fullest allowance for the fact that seasonal climatic conditions were exceptionally unfavourable for the spread of infection from July till October it seemed certain that disinfection was remarkably successful. This success was all the more definite because little was done to disinfect clothing or to administer vaccine though the authors consider that both of these measures ought to have been adopted.

VIEL, B & ROMERO H Dos epidemias de tífus exantemático [Two Epidemics of Exanthematic Typhus (In South Chile)] *Rev Med Chile* 1945 Oct. v 73 No 10 847-54 2 figs

The interesting feature of these two epidemics is the striking contrast between the ease with which one of them was controlled by treating all the huts in the affected area with a 10 per cent. DDT powder and the elaborate organization needed to deal with the earlier one which occurred before DDT was available.

ECKER, R. S GILLIAM, A. G SNYDER, J C., YEOMANS, A. ZARAFONETIS, C. J & MURRAY, E. S The Effect of Cox-Type Vaccine on Louse-Borne Typhus Fever An Account of 61 Cases of naturally occurring Typhus Fever in Patients who had previously received One or More Injections of Cox-Type Vaccine. *Amer J Trop Med* 1945 Nov v 25 No 6 447-62, 1 fig [26 refs]

The authors working with the U.S.A. Typhus Commission made a careful study of the effects of an ether-extracted Cox type vaccine in a large group of persons exposed to infection by louse-borne typhus in the course of their work at the Cairo Fever Hospital. The standard of protection aimed at was a course of three doses of vaccine at weekly intervals followed by single stimulating doses at intervals of 4-6 months. Persons exposed to the same risk, who had refused vaccination, served as controls. Every possible care was taken to avoid the fallacies incidental to observations of this kind. Complete data are recorded in tabular form for 61 patients who contracted typhus after receiving varying numbers of doses of the vaccine the only death was in the case of a man aged 35 years who had received a single dose three days before the onset of the illness. The chief findings are shown in the following table —

Doses of Vaccine	Interval since last dose	Number of patients	Average length of illness (days)	Severity of attack				Fatal
				Very mild	Moderate	Severe	Very severe	
3 or more	21 or more days	28	10½	21	5	0	0	0
2	21 or more days	7	12	4	3	0	0	0
1	21 or more days	11	12.7	2	8	1	0	0
1	Less than 12 days	17	15	4	5	4	0	1
1		10	15½	0		2	0	3
Nil								
Other hospital patients treated at same time and of same age group				1	12	18	5	8
No Vaccine		44						

A careful statistical study showed that the disturbing influence of age could be excluded. The findings suggested that administration of the vaccine during the incubation period might lessen the severity of the illness so that a campaign of vaccination is recommended even during an epidemic. There was no evidence of a falling off in the efficacy of the vaccine up to 325 days after the last dose, but the data do not justify conclusions with regard to the duration of the protection.

MOOSER, Hermann Die Beziehungen des murinen Fleckfiebers zum klassischen Fleckfieber

This book is reviewed on p. 611

BOVENTER, K. & FISCHER, R. Ueber das Rattenfleckfieber (endemisches gulariges murines Fleckfieber) in Sizilien [Rat Typhus (Endemic, Mild, Murine Typhus) in Sicily] *Deut. Tropenmed. Zeitschr.* 1944 Jan. 1 v. 48 No. 1/2, 1-7

The authors describe four cases of rat typhus seen in Sicily in December 1942, and the first six weeks of 1943. The diagnosis was made on the strength of the symptomatology, the epidemiological conditions of occurrence, and the positive Weil-Felix reaction. Animal-inoculation experiments could not be carried out. Italian observers had already reported the occurrence of 31 cases of the disease in Sicily.

The authors classify the typhus fevers as louse typhus, rat typhus, tick typhus, and mite typhus. They state that the transmitting vectors of rat typhus are the rat and the rat flea. [Presumably they regard the name flea typhus as unsuitable because they accept the view that infection is often acquired through ingestion of food contaminated by the urine or faeces of infected rats, but even assuming that this view is well founded the more familiar name murine typhus would be preferable.]

PASCALE, H. & CRUZ, E. Considerações sobre rickettsioses nos municípios de Itaparatiba, São João da Boa Vista e São José do Rio Pardo (Contribuição ao estudo das Rickettsioses) (A Study of the Rickettsial Diseases of the Municipalities of Itaparatiba, São João da Boa Vista, and São José do Rio Pardo (South Brazil)) *Arquivos de Hig. e Saúde Pública* São Paulo 1945 June v. 10 No. 24 287-304 English summary (5 lines)

The authors have made a diagnosis of flea-borne Typhus Murinus or Brill's disease in six cases in São João da Boa Vista in 1944 and in seven cases in

São José do Rio Pardo since 1941. The Weil-Felix reaction (*Proteus* O\19) was positive in high titres and the epidemiological conditions were in keeping with the diagnosis. Tables are given of all the cases in which positive Weil-Felix reactions were observed in both localities since 1939. In the former four persons gave positive reactions with *Proteus* O\K in 1939 at titres of 1-100 to 1-200 and two other persons reacted with *Pr* O\19 at titres of 1-100 and 1-400 respectively. No other positive reactions occurred till 1944 when all the reactions were of the OX19 type at titres of 1-1 600 and over. In the latter area during 1939 six positive reactions were observed. They were (1) O\K 1-100 (2) OXA 1-200 (3) O\A 1-800 and O\19 1-400 (4) O\A and O\19 1-1 600 each (5) O\K 1-100 and O\19 1-400 (6) O\19 1-100. In 1940 the O\19 reactions greatly predominated, and in the later years no O\K reactions have been observed. [This change in the type of the serological findings is curious. It may even give rise to a suspicion that the *Proteus* strains used in the tests were not always true to type.] *John W. D. Megaw*

SMADEN J. E., RIGHTS F. L. & JACKSON Elizabeth B. Studies on Scrub Typhus. I. Soluble Antigen in Tissues and Body Fluids of Infected Mice and Rats. *J. Exper. Med.* 1946 Feb 1 v 83 No 2 133-46 [17 refs.]

The studies described in this paper have already been reported in summarized form to the U.S.A. Typhus Commission in August 1944 and March 1945.

Two strains of typhus rickettsiae were studied, Imphal No 8 and a Calcutta strain. These had been passed 6-7 times through rabbits and afterwards were maintained by transfer through yolk sacs. Material obtained from yolk sacs of the 12th to 43rd passages was used to inoculate mice and white rats by the intravenous route and cotton rats by the intracardiac route. The doses given caused death on the 4th to 6th day. Heart blood, pleural fluid, lung and spleen tissues of the infected animals were used in the experiments for the detection of the antigens. The methods of preparation are described; they included grinding of the tissues and extraction with ether.

Antigens obtained from the tissues of mice infected with one or other strain gave the same complement-fixation responses as sera of mice immunized with either strain and cross-immunity tests also showed that the strains could not be distinguished from each other.

Antigen prepared from the lung tissues of infected mice was found to be strictly specific when used in complement-fixation tests. The reactions with scrub-typhus sera were positive; those with epidemic and endemic sera were completely negative.

Serum and pleural fluid from mice that had died on the 4th to the 6th day contained the specific antigen, but when the mice had survived for longer periods, as happened after intraperitoneal inoculation, no appreciable amount of antigen could be detected, presumably because of a low rate of production and of the longer time that was available for the formation of neutralizing antibodies.

By high-speed centrifugation of the ether-extracted tissue suspensions it was found that the antigens were present almost exclusively in the soluble form in the supernatant fluid. The authors suggest that the antigens had been released because of damage to the rickettsial bodies in the process of grinding and extraction.

Although the sera of the infected animals were much less infective than their tissue suspensions they contained appreciable amounts of complement-fixing antigens which persisted in undiminished quantity after high-speed centrifugation and therefore appeared to be in soluble form. Heating the

[June 1946]

serum and pleural fluid to 56°C. for half an hour did not destroy the antigens. In ether-extracted tissue suspensions there was a variable rate of diminution of the antigen during storage at 5°C.

BROWNING J S RAFAELL M KLEIN E F & CONLEY, A. Scrub-Typhus.
Amer J Trop Med. 1945 Nov v 25 No 6 481-92 2 charts. [12 refs.]

This study is based on 173 cases of scrub typhus admitted to hospital from various places in the New Guinea Archipelago. There were six deaths, all of which occurred among 16 patients admitted from one locality within a period of three weeks. Infection was thought to have occurred while they were sitting on the only patch of grass in the neighbourhood.

The Weil-Felix (OAK) test was of great value in diagnosis but a titre of 1-80 was seldom reached before the ninth day and in one group of patients from an isolated area the reaction was uniformly negative.

Some of the chief features of the disease were as follows (figures in brackets are percentages).—Headache (92) orbital pain (82) chills or chilly feeling (47) eschar (80) usually on the legs or in the axillae maculo-papular rash (35) and subconjunctival haemorrhage (33). Leucopenia was not frequent but relative lymphocytosis was usual. A pulse rate over 120 per min. usually indicated the presence of a complication.

Among 112 patients examined by electrocardiography about a month after the onset, 18 were abnormal but 40 per cent. of these became normal within a month.

The chief complications in the acute phase were (in percentages) impaired hearing (20) pulmonary (17) abdominal distension (10) epistaxis (5) arthralgia (4) and retinal haemorrhage (2). In convalescence there were seven cases of psychoneurosis and six of neurocirculatory asthenia both of these conditions were regarded as due largely to anxiety resulting from reading or hearing reports of permanent damage to the heart. There were four cases of myocardial damage, but the authors believe that there will be no permanent sequelae.

MEXDELL, T H. Scrub Typhus Fever (Tsutsugamushi Disease) in New Guinea. Report of 75 Cases. *Amer J Med. Sci.* 1946 Jan v 211 No. 1 9-22.

This study of scrub typhus is based on 75 cases of which two were fatal, seen in North New Guinea during the months August September and October 1944.

The incubation period was known in only one case in which it was 21 days. The area where the infection was contracted consisted of grass and scrub land 58 of the cases occurred during the first half of the period, before the site was cleared, and after three months the disease ceased to occur.

The incidence of the chief features was as follows figures in brackets are percentages.—The eschar (86) was single except in seven patients the usual sites were the axilla, scrotum and groin. The macular rash (78) was on the trunk and limbs to a lesser extent on the face. Adenopathy (85) was most pronounced in the glands associated with the eschar. Splenomegaly occurred in 37 cases. Conjunctivitis (71) affected the palpebral conjunctiva, from which it extended with diminishing severity towards the cornea. In many cases there were subconjunctival haemorrhages. Deafness (35) was transient except in one case. The central nervous system was specially involved in nearly half the cases. One patient had a severe post typhus psychosis with ultimate recovery and two others had a temporary psychosis in convalescence.

lasting a few days Rickettsial pneumonitis or bronchitis occurred in 38 cases (51) Hypotension was a constant feature. Leucopenia was usual with relative lymphocytosis

The Weil Fehx test (OAK) was carried out in 34 cases it was negative in three in eight the titre was 1-40 and in 23 it was 1-80 or over

At autopsy in the two fatal cases a vasculitis with perivasculitis was the chief feature the vessels chiefly affected were the smaller ones of the brain lungs and heart and the chief changes were in the reticulo-endothelial system

There was a pronounced tendency to haemorrhages.

Sodium chloride (6 gm daily) was given as a routine therapeutic measure.

The convalescent period ranged from one to six months Stress is laid on the need for reassuring the patients to prevent disabling neuroses.

AGRESS C. M & EVANS E. R. Clinical Survey of Eighty-Six Cases of Scrub Typhus. *Bull U.S. Army Med Dept* 1946 Feb 15 No 2 163-9

The authors studied 86 cases of scrub typhus of which 79 occurred among Chinese soldiers in Assam and North Burma between November 1943 and September 1944 The case-fatality rate was 10 per cent. The average duration of the illness before admission to hospital was seven days The clinical picture was not unusual in any important respect

The percentage incidence of some of the chief features was as follows headache 86 backache 73 cough 40 deafness 28 eschar 78 lymphadenopathy 94 conjunctivitis 65 remittent type of fever 60 intermittent type 40 termination by lysis 100 and positive *Proteus* OAK agglutination, 1-40 or over 80

A definite rash was seen in 31 per cent of the patients including 10 in whom there was only generalized erythema the types of rash observed were macular 18 cases maculo-papular 12 erythematous 10 and papular 1 [Presumably in a number of the cases the rash was partly macular and partly maculo-papular] The rash extended to the face in three cases the palms and soles were never affected. There was often a short recrudescence of fever after the temperature had been normal for two or three days.

The leucocyte count ranged from 1 900 to 26 400 per cmm. the average count in the 1st week was 9 800 in the 3rd week it was 12 100 The percentage of lymphocytes ranged from 9 to 75 the average was 29 per cent in the 1st week, and 43 per cent. in the third.

Among 19 cases tested in the 2nd week the OAK reaction was positive (1-25 to 1-1 600) in 11 in the 3rd week it was positive in 13 of 18 cases tested in the 4th week it was positive in 27 of 30 cases tested and in the 5th week it was positive in all the 10 cases tested.

Sulphathiazole was given to 16 patients but it only added to their discomfort. Plasma given to 10 patients caused no striking improvement

ANDREW R. Fluid Balance in Scrub Typhus. *Med J Australia*. 1945 Dec. 15 v 2, No 24 432-4

The interesting observations described to this paper are based on a study of 11 severe cases of scrub typhus in North Queensland. The infection in 10 of the patients was contracted on the same day Sudden diuresis occurred on the 10th-16th day of the disease in 10 of the cases and on the 32nd day in the remaining case. The average daily fluid intake before diuresis occurred was 97 oz and the output [presumably urinary] was 44.7 oz. On the first day of

diuresis the average output rose suddenly to 96.4 oz. though the intake had risen by only 20 per cent. to 116.7 oz. The diuresis occurred on the average about three days before the temperature became consistently less than 99°F and it was accompanied by a striking improvement in the general condition of the patients though at first sight they looked worse because of the sudden disappearance of the oedema that had masked the pronounced degree of anaemia.

No obvious cause could be found for the diuresis in a few cases the blood pressure had been observed before and after the event, but no significant difference was detected, traces of albumin were found in the urine of three patients but there was never anything approaching nephritis. The serum proteins were within normal limits in the cases tested from this point of view.

The findings are regarded as reinforcing the warnings against further deranging the fluid balance in patients with scrub typhus by intravenous injections more than five or six pints of liquid daily by the mouth are considered unnecessary.

The climate of the hospital area was hot and humid, the altitude was about 2,000 feet.

[Climatic conditions must be taken into account in estimating a suitable fluid intake.]

DONEGAN E. A Ocular Findings in Tropical Typhus (Tsutsugamushi or Japanese River Fever). *Brit. J. Ophthalm.* 1946 Jan v 30 No. 1 11-19

The eyes of a total of 101 cases of tropical typhus were examined, and the ocular changes may be summarized as follows—In the acute stage the conjunctivae are generally hyperaemic without involvement of the cornea, clearing about the 14th day. The fundi typically show a disk in which there is pathological hyperaemia with an overlying central vitreous haze with its margins blurred in at least two quadrants often accompanied by swelling. The vessels show little or no change even in patients with marked cerebral symptoms as they give no suggestion of venous stasis. The hyperaemia disappears once the acute stage of the disease is over and the fever has subsided. The vitreous haze then clears about the end of the third week. The last sign to disappear is the marginal blurring which may persist in some cases for more than a month after the subsidence of systemic signs of the disease. The interpretation placed on the ocular signs is that of a vascular upset not a neural or neuroglial involvement by invasion of the nerve tissues by the rickettsial bodies. There appears to be only very slight reaction to the organism which would explain the absence of post-neuritic changes due to fibrosis of the optic nerve and retina. It is not understood why toxic substances which have done so much harm to renal and hepatic tissues should allow the more delicate cells of the brain and retina to escape obvious permanent damage.

IRONS E. N & ARMSTRONG C. A. Jr Relation of the Weil-Felix Reaction to the Clinical Course of Tsutsugamushi Disease. *Bull. U.S. Army Med. Dept.* 1946 Jan. v 5 No. 1 85-94 8 charts. [16 refs.]

The authors studied the Weil-Felix (OXX) response in 74 cases of tsutsugamushi disease of which seven were fatal. The conclusion is stated as follows—“The incidence of Weil-Felix reaction was inversely proportional to the severity of the illness. 94.5 per cent. of the moderately severe, 90 per cent. of the severe, but only 29 per cent. of the fatal cases showed a Weil-Felix reaction during the course of the disease. [This conclusion is hardly justified by the facts supplied—the only significant figure is that relating to the fatal cases

but the day of death is stated in only two instances in one of which death occurred on the 15th day and the reaction was positive while in the other death was on the 16th day and the reaction was negative. Seeing that the delay in the appearance of a positive reaction averaged 17 days and in some cases was up to 24 days there is no justification for regarding the negative reactions among the fatal cases as being comparable with those among survivors. Also the classification of the cases as 'severe' when the duration of the fever was 18 days or more and as 'moderately severe' when it was less than 18 days irrespective of all other considerations is open to criticism.

A really valuable feature of the paper is the set of seven charts which show the relationship between the rise and fall of the titres and the course of the illness.]

BENGTSON Ida A Apparent Serological Heterogeneity among Strains of Tsutsugamushi Disease (Scrub Typhus) *Pub Health Rep* Wash. 1945 Dec 14 v 60 No 50 1483-8

The complement fixation titres of sera of animals and human beings infected with different strains of *Rickettsia orientalis* were found to vary greatly according to whether a homologous or heterologous antigen was used in carrying out the test. Most of the experiments described were done with Karp (New Guinea) and Gilliam (Assam-Burma border) strains. A Seerangayee strain (Malaya) was used in some of the tests it had been found more virulent for guinea-pigs than the other two strains whereas the Gilliam strain was the most virulent to chick embryos in yolk-sac cultures. The virulence of an Imphal (Assam) strain for chick embryos was exceptionally low and altogether great differences in virulence were found.

A typical example of the variations in the complement fixation titres is as follows.—The serum of a guinea-pig infected by the Gilliam strain gave a titre up to 1-2 048 with Gilliam antigen and up to 1-8 with Karp antigen. So also a Karp-strain serum gave a titre of 1-250 with Karp antigen of 1-4 with a Gilliam antigen and of 1-16 with a Seerangayee antigen.

The sera of patients who had been accidentally infected by Karp and Gilliam strains gave correspondingly different responses according to whether a homologous or heterologous antigen was used. In every case the response with the same antigen was at a titre which was at least 100 times greater than that given when the other antigen was used.

The Karp and Gilliam antigens were used in tests of sera from patients suffering from epidemic endemic and Rocky Mountain-spotted-fever infections and in every case the reaction was negative.

Several groups of serum from cases of tsutsugamushi disease in the Pacific area were tested all gave positive fixation against the Karp or Gilliam antigens.

TOPPING has already shown that cross immunity exists between guinea-pigs that had been infected with the Karp Gilliam Seerangayee and another strain it remains to be found whether there is an association between the fixation titre and the degree of immunity [See the comment on the paper by ZARAFONETIS above]

John W D Megaw

CHARTERS A. D Tick-Typhus in Abyssinia *Trans Roy Soc. Trop Med & Hyg* 1946 Feb v 39 No 4 335-42 1 chart. [13 refs]

This is claimed to be the first description of tick-borne typhus in Abyssinia though the author mentions that the Army Pathological Laboratory Service in its *Current Notes* for December 1941 stated that the disease occurs there and that the vector is *Rhipicephalus sanguineus*.

reducing sugars. In the course of an investigation on plasma substitutes one of the authors observed that pyrogenic solutions of gelatin were rendered non-pyrogenic by heating with potassium permanganate or hydrogen peroxide. Further work has shown that if pyrogenic solutions are heated at 100°C. for 60-120 minutes in the presence of 0.1 M hydrogen peroxide their pyrogenic properties are abolished and at 0.01 M concentration are decreased. The change is not due to alteration of pH.

The authors suggest, therefore, that treatment with hydrogen peroxide may be of practical use so long as the hydrogen peroxide does not adversely affect other constituents of the solution and so long as the amount used is not sufficient to destroy the pyrogens and leave a deleterious excess.

Charles Wilcocks.

BACILLARY DYSENTERY

ELSON K. A. PEPPER, D. S. & FORRESTER, J. S. The Treatment of Bacillary Dysentery in Chinese Soldiers with Sulfaguanidine and Sulfadiazine. *Amer J Med. Sci.* 1946 Jan. v 211 No. 1 103-9 3 charts.

From June to December 1943 334 Chinese soldiers suffering from acute bacillary dysentery were treated in rotation as admitted to a hospital in North Eastern India with (a) a placebo or (b) sulphaguanidine 3.5 gm. four hourly or (c) sulphadiazine 3 gm. initially and then 1 gm. four hourly. The diagnosis was clinical the patients were graded as slightly moderately or severely ill stool specimens were examined and bacteriologically cultured early after admission and a confirmatory bacteriological diagnosis was established in 25 per cent. of the cases which were found equally distributed in the three treatment groups.

The average periods of fever of diarrhoea, and of hospitalization were unaffected by the alternative treatments with sulphaguanidine sulphadiazine or the placebo and the authors consider whether this divergent result from the findings of other workers was due to the late stage at which the cases presented themselves (treatment was begun on the average, 5 days after the onset of symptoms) or to the predominantly mild form of the bacillary dysentery from which most of the patients suffered. They are not convinced that either explanation is the correct one. They observed no toxic effects from sulphaguanidine but the renal complications from the use of sulphadiazine were frequent and, at times, alarming. Two fatalities might have resulted from the latter but for the available facilities for ureteral lavage and it is concluded that, under the climatic and other conditions of this study the dangers of sulphadiazine in the dosage used exceeded those of the disease for which it was given.

A. R. D. Adams

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

REES, C. W. & REARDON, Lucy V. Comparative Yields of *Endamoeba histolytica*-Organism from Soluble and Insoluble Ingredients of Egg White in Freshly Prepared and Stored Medium. *Amer J Trop Med* 1945 Mar v 23 No 2, 109-14 [14 refs.]

Having shown that good growth of *E. histolytica* can be obtained in a modified LES [Locke-egg-serum] medium in which the whole egg is replaced by egg white enriched with cholesterol and vitamins, the authors attempted to

discover whether the essential ingredient of the egg white was a water-soluble fraction or a heat-coagulable fraction. The egg white was poured into boiling Locke's solution and the coagulum separated by centrifugation. Neither the Locke's solution containing the uncoagulated ingredients nor Locke's solution to which the coagulum had been added were able to replace the Locke's solution and egg white of the modified LES medium. Strangely enough this was also true of the two fractions when combined in a single medium. The operation of separating the two fractions by heat had altered the amoeba nourishing properties of the egg white. Egg yolk also was not a substitute for egg white. In these cultures only a single bacterium (organism *f*) was present and it grew without any difficulty. It was shown that permeable membrane bags containing Locke's solution and organism *f* when inoculated with *E. histolytica* allowed growth of the amoebae when the bag was kept in contact with an egg slant overlaid with Locke's solution in which organism *f* was growing. Presumably amoeba nourishing materials liberated from the egg slant diffused through the membrane in sufficient quantities to permit growth of the amoebae. It was found that though coagulated egg white favoured growth of amoebae when it was confined to the base this was not the case when it was contained in the overlay.

Another result has been the demonstration that early spring or summer eggs or pullet egg white yield a more favourable medium than fall [autumn] or winter eggs. It was found that if medium is stirred it loses its properties if oxygen is absorbed as through a cotton stopper. If the stopper is rubber and the residual oxygen is absorbed by pyrogalllic acid deterioration of the stored medium does not occur. Under these anaerobic conditions of storage ovomucoid diffuses from the egg white base into the overlay with the result that the oxygen free overlay is capable of yielding a good growth of amoebae. The results appear to indicate that fresh egg white base acting in conjunction with organism *f* is concerned in the oxygen potential of the medium. Though the investigation has yielded interesting results it has not shown what fraction of egg white is responsible for growth of the amoebae. C M Wenyon

KERSHAW W E. The Diagnosis of Amoebiasis. *Brit Med J* 1946 Mar 2 305-7

Amoebiasis is acquired much more commonly by Europeans in the East than is generally realized. The seriousness of the infection is not fully appreciated there or in the United Kingdom. Of 300 cases seen in Ceylon one-half were diagnosed after three and the remainder after eight to twelve stool examinations but even this number of examinations cannot be considered as adequate for the detection of every case. Difficulty was experienced in recognizing cysts which were more readily identified after a modification of Faust's method of concentration had been introduced. This primarily had the virtue of freeing cysts from the matter which obscured their identification in fresh faecal material. The author considered that there was a regular rhythm in the appearance of amoebae pre-cystic amoebae and cysts in his cases both acute and chronic. Sigmoidoscopy was not of great value in the diagnosis of clinically latent cases. A R D Adams

SOKOLOFF B. New Aspect in Treatment of Amebiasis. *Rev Gastroenterology* 1945 Nov-Dec. v 12 425 [Summary taken from *J Amer Med Ass* 1946 Mar 2 v 130 No 9 607]

Sokoloff found that lactic acid even in a weak solution of 1 : 1 000 impedes the multiplication of protozoa including amebas. Since ingested lactic acid is

actively absorbed in the small intestine and therefore is of little use in the treatment of infections of the large intestine a special anhydrous form of lactic acid, trilactic was developed. Trilactic dissolves in water slowly and for this reason reaches the colon and caecum without being affected greatly by the gastric juice. Research has demonstrated that trilactic has a therapeutic effect in animals infected with pathogenic bacteria. Rats infected with *Endameba histolytica* were submitted to trilactic therapy. Although they had only a mild form of amebiasis, their stools showed presence of trophozoites and cysts. These disappeared after seven days of treatment with trilactic. The animals seemed to have been completely cured. During the last five years trilactic has been tested on a number of patients with amebic infection. In many instances they received the trilactic treatment after emetine had failed to eliminate completely the pathogenic ameba, or when the patient had experienced a toxic reaction from this drug. In a few instances trilactic was administered after protracted iodine therapy when stools still showed presence of the cysts. Such combined therapy showed the most satisfactory results not only in the complete elimination of the ameba but also in the prompt restoration of the normal bowel movement. Sixty-two patients affected with acute and chronic amebic infections have been treated with the anhydrous form of lactic acid known as trilactic. Complete recovery was obtained in 36 improvement in 15 and negative results in 11 patients.

DUNLOP E. E. Surgical Treatment of Dysenteric Lesions of the Bowel among Allied Prisoners of War in Burma and Thailand. *Brit Med J* 1948 Jan. 28 124-7

Dysentery levied a heavy toll amongst prisoners of war working on the Thailand-Burma railway. Numerous prisoners suffered simultaneously from dysentery, malaria, tropical ulcer and gross malnutrition and the medical officers had to contend with shortage or complete absence of specific amoebicidal drugs, lack of facilities for microscopy and for proper nursing and feeding of the patients and with the action of the Japanese in forcing men with established dysentery to continue working. In consequence many of the patients developed very severe lesions with a tendency to become chronic and emetine-resistant, or to relapse almost immediately on the cessation of treatment. In the acute phase often with 60 or more motions daily there was gross cellulitic swelling of the large bowel with tumour formation in the caecal region, sometimes leading to sloughing, perforation and peritonitis. In the chronic cases scarring, thickening and fibrosis were often found in the caeco-appendicular region at operation. Structure formation after sloughing was met with principally in the rectum. Drugs, in so far as they were available, had been administered to the patients in quantities normally curative: bowel washes of saline, quinine, yatrien, silver nitrate etc. had also been used but had given disappointing results owing to the intense irritability of the inflamed bowel. The failure of medicinal treatment and the wretched plight of the patients led to a trial of surgical measures for the relief of pain and tenesmus. In the more acute cases appendicostomy proved most effective, permitting thorough flushing of the large bowel, whilst in the cases of long standing with a grossly damaged colon, ileostomy was the method of choice as it afforded complete rest to the large bowel. Appendicostomy was performed in 8 cases, ileostomy in 14, caecostomy in 1 and partial resection of the colon in 3 cases. Three deaths occurred amongst the ileostomy patients and one after resection of the right half of the colon in a patient who had suffered from an amoebic abscess of the liver together with a carcinoma of the hip. Six of the eight appendicostomy patients regained good health, with negative stools: in one case the fistula has been closed and in another

it was allowed to close spontaneously. Seven of the ileostomy cases have regained their health eating a normal diet and doing light work, and needing only a weekly colon wash-out. The others are improved. Only one case so far has been closed, after two years rest of the bowel. In other cases closure was deferred until after evacuation from Thailand. The need for a post-operative course of emetine is stressed, as there is a danger of spread of amoebic infection to the abdominal wall.

[In the same number of the *British Medical Journal* is a paper by Capt. S. S. PAVILLARD on Medical Experiences in Siam (this *Bulletin* 1946 v 43 489) which gives a vivid picture of the terrible conditions under which medical officers had to work in Siam.]

CLARK R. H. P. & DUTTA D. K. Pneumo-Peritoneum in the Investigation of the Right Costo-Hepatic Area. *Indian Med Gaz.* 1945 Nov v 80 No 11 554-6 6 figs on 4 pls

Pneumo-hepatography is a valuable diagnostic aid in determining whether a lesion lies above or below the diaphragm or whether distortion of a clearly visualized diaphragm is due to deformity of the liver itself. The authors have employed the procedure on 35 occasions without ill effect except in the case of one elderly patient with a rigid emphysematous chest who suffered pain and dyspnoea for six hours. Emphysema should therefore be added to cardiac insufficiency and an acute infection as a contraindication to pneumo-peritoneum. The methods of inducing pneumo-peritoneum have been reviewed by MAXFIELD and McILWAIN (*Radiology* 1944 v 42 436). ASTLETT and JARMAN (*Lancet* 1945 v 1 304) report fatalities in two cases of pulmonary tuberculosis one after the 4th and the other after the 14th peritoneal refill. RICHARDS (*Lancet* 1945 v 1 414) commenting on these adds a record of another fatality due to air embolism on the fourth day after pneumo-peritoneum. Carbon dioxide may be used more safely than air as it is rapidly absorbed but on this account the X-ray examination would have to be made immediately after the injection. MAXFIELD and McILWAIN have injected 3 000 cc. or more of this gas into the peritoneal cavity.

The authors give an account of their technique using a pneumothorax apparatus connected to an 18 or 20-gauge needle. They found 350 to 500 cc of air sufficient in Indians of light build to separate the diaphragm and liver and they fluoroscoped the patients in the standing position 4 to 8 hours after its introduction. Both the liver and the spleen may be visualized as the gas accumulates under the diaphragm by putting the patient on one side or the other its distribution may be varied.

Notes are given of five illustrative cases where pneumo-hepatography materially assisted in the diagnosis of obscure liver conditions and reproduction of 14 X-ray pictures illustrates the salient features of these cases. The authors conclude that pneumo-hepatography is a valuable and safe aid to diagnosis.

KARL W. Hepatic Abscess Secondarily Infected. Penicillin Treatment. *Indian Med Gaz.* 1945 Sept. v 80 No 9 451-2.

A British officer aged 35 was transferred to the author's care on 20th November 1944 with a history of illness of about one month's duration which had been diagnosed at first as pneumonia and diaphragmatic pleurisy and had been treated with sulphapyridine 26 gm. in 6 days. Soon afterwards amoebic hepatitis had been diagnosed and ten injections of 1 grain of emetine hydrochloride had been given from 29th October to 7th November. On 30th October the liver margin reached to the level of the umbilicus and X-rays showed

elevation of the right side of the diaphragm the patient had irregular fever and his leucocyte count was 17,200 cells of which 86 per cent. were polymorphonuclears. Sterile fluid was aspirated from the right pleural cavity. Next day October 31st, thin red fluid containing *Extemoebe histolytica* was aspirated from the upper part of the right lobe of the liver.

By 10th November the liver dulness had decreased to the level of the 4th anterior intercostal space above and to three fingerbreadths below the costal margin his irregular temperature had settled and the leucocyte count was 7,400. On 17th November fever recurred, liver dulness reached upwards to the 2nd rib and X-rays showed right pleural effusion. Next day 240 cc. of haemorrhagic fluid were aspirated and 150 cc. on the following day (November 19th).

On transfer to the author's care on 20th November liver dulness extended to the 4th rib and to 1 in. below the level of the umbilicus the leucocyte count was 13,200. A second course of 12 injections of emetine hydrochloride was given from 22nd November to 5th December his general condition improved and he remained afebrile. On 4th December 20 cc. of chocolate-coloured pus were aspirated from the right chest it contained pus cells but was sterile. The liver dulness now reached to the 7th rib in the mid-axillary line and to three fingerbreadths below the costal margin.

On 7th December he had a rigor followed by irregular high fever no malaria parasites were found in the blood. On 11th December he had severe right shoulder pain the leucocyte count was 16,400 with 76 per cent. of polymorphonuclears. Emetine bismuth iodide, 3 grains daily was given without benefit. On 15th December X rays showed a large cavity with a fluid level at the 4th rib his general condition was grave.

On 18th December two pints of pus were aspirated and 200,000 units of penicillin in 90 cc. of saline were injected into the cavity the pus was thick, grey and very foul-smelling and in cultures showed *Bacterium coli*, *Staphylococcus albus* and *Bact. alkaligenes*. Sulphathiazole 6 gm. daily was given from the 18th to the 25th December a total of 40 gm. On 20th December the leucocyte count was 20,000. Fever persisted after the course of sulphathiazole and on 29th December X-rays showed a fluid level at the 5th rib. Next day 2½ pints of thick yellow sterile pus without foul odour were aspirated and 200,000

units of penicillin in 150 cc. of saline were injected into the cavity. On 28th December the abscess cavity was opened and drained by a de Pezzer catheter capacity was estimated to be 5 pints and about 3 pints of light-yellow odorless, sterile pus were evacuated. By 8th January 1945 the size of the cavity was 6 ounces and 3 weeks later it was 2 ounces, while after a further 2 weeks there was no discharge and the wound had almost healed.

The author concluded that "either penicillin was the chief sterilizing agent or the combined effect of the two drugs was a mutually reinforcing one and amounted to more than the sum of the separate actions." J. F. Corson

the brain of a guineapig was found to be infective 36 months after spirochaetes had disappeared from the circulating blood. The author's experiments also show that this "Chiffalo" strain of spirochaetes isolated in 1933 still preserves the same virulence after 313 passages in guineapigs *E Hindle*

TUCKER, W. A. L. A Report on the Treatment of Tick Relapsing Fever with Sodium Penicillin. *East African Med J* 1946 Jan v 23 No 1 13-18

The author refers to the marked increase of tick-transmitted relapsing fever (*S. duttoni*) in East Africa, especially in the Western and Buganda Provinces of the Uganda Protectorate and to the comparatively unsatisfactory results of arsenical treatment in this disease. Accordingly 36 typical African cases were selected from admissions to hospital and treated with sodium penicillin. The 36 cases comprised 16 adult males 9 adult females (4 pregnant) and 11 children. All showed spirochaetes in the blood before treatment was started, and were given doses of 5 000 to 25 000 units of sodium penicillin every four hours usually intramuscularly but in four cases intravenously. A total dosage of at least 300 000 units seemed to be necessary to effect a cure. For comparison 19 patients were treated with either neoarsphenamine or sulpharsphenamine.

In the penicillin series the average time for the temperature to return to normal was 23.4 hours and the blood films became negative in an average of 20.1 hours. The series treated with arsenicals took an average of 16.7 hours for the temperature to return to normal and 17.4 hours for the blood to become negative.

Three arsenic resistant cases were treated with penicillin and all relapsed. Relapse occurred in 27.7 per cent. of all the penicillin cases, and in 31.5 per cent. of those treated with arsenicals.

The author concludes that penicillin does not seem to be more effective than arsenical preparations in the treatment of this strain of relapsing fever but that penicillin is the drug of choice when jaundice is a prominent symptom.

YAWS

IBARRA PEREZ, R. & GONZALEZ PRENDES M. A. La frambesia en Bayamo (Frambuesa, pian, yaws o bubas) [Yaws in Bayamo (Cuba). *Rev. Sifilografía, Leprología y Dermatología* Marianao Cuba. 1945 Dec. v 2 No 4 206-18]

Yaws it is said was practically unknown in Cuba before Professor Castelló diagnosed it in 1932 in three children of one family in Sagna de Tánamo. Since then the number seen has increased, particularly in the Province of Oriente. Others say that it has been present in Cuba since 1895 introduced from Haiti.

A Commission to study the question was constituted in 1937 and that year 274 cases were diagnosed 133 of them in Baracoa and 103 in Sagna de Tánamo. By the following year the total was 1 125 of which 191 were in Baracoa, 111 in Sagna de Tánamo and 567 in Bayamo. In 1941 99 new cases brought the Bayamo figure to 666 and by 1944 there were 845. It has been generally stated and believed that yaws is largely a disease of the black races but the authors' investigations go to show that under the same conditions the white races are every bit as susceptible. In fact of these cases 71.9 per cent. were whites 19.2 per cent. were half-castes and only 8.9 per cent. were negroes.

1 VARRA PEREZ R. & GONZALEZ PRENDES M A Lepra en Cuba [Leprosy in Cuba.] *Rev Sifilografia Leprologia y Dermatologia* Marianao Cuba. 1945 Dec. v 2 No 4 252-72 [29 refs.]

The subject dealt with is comprised in three papers concerned with different aspects of the question. The first on Leprosy in Havana, is largely historical of the epidemiological and treats of the founding of Havana in 1519 its geographical position and general topography. From available records it would appear that leprosy was known to exist there in the latter part of the sixteenth century and its introduction is ascribed to colonizers and slaves. In 1681 the children's Hospital for lepers was founded the attendants being Sisters of the Holy Family. The town now comprises 43 Wards and lepers may be found in all parts. The incidence of leprosy is estimated as 0.47 per mille inhabitants—320 cases in a total population of 676,376. Control is maintained and those who are properly looked after in their homes are segregated contacts are kept under surveillance with a view to protecting the healthy public from contamination.

In the second paper gives more statistical information on the general prevalence of leprosy in Cuba. The area of the island is given as 114,524 sq km. 2,539 lepers are registered and it is thought that the actual figure is for the island about 4,000. Havana itself has the highest incidence 5.7 cases per 100 population. Pinar del Rio the lowest 0.48. Taking the figure of 4,000 as fairly correct the incidence of leprosy in Cuba would be on an average 3.49 per 100,000 sq km.

The third contribution deals with the incidence of leprosy in Cuba relative to the population. In this paper the authors revert to the figure of 2,539 cases previously given which with a population of four and three-quarter millions gives a rate of 5.3 per 10,000. Of the total cases 592 are in hospitals and 1,947 free to move about. In the provinces of Camagüey and Cienfuegos the proportion of ambulant cases is 5.15 per 10,000. Havana has 3.82 and Pinar del Rio fewest with 1.66. After giving the above figures the authors reiterate the statement of the preceding paper that the probable number of lepers in Cuba is about 4,000.

2 CASTRO PALOMINO J & ALFONSO Y ARMENTEROS J La lepra en el dispensario Saenz. Estadística de los casos atendidos durante dos años [Statistics of Lepers attended at the Saenz Dispensary (Cuba) 1943-45.] *Rev Sifilografia Leprologia y Dermatologia* Marianao Cuba. 1945 Dec. v 2 No 4 249-51

Together 119 new cases have been seen in the 2 year period. Sixty were males & 59 were females. As regards type of disease, 65 were lepromatous 22 tuberculoid 12 non-characteristic and 20 unclassified. It has been the policy to examine them all bacteriologically to make histological and biological investigations and to estimate the blood sedimentation rates. Seventeen have been transferred to other dispensaries leaving 102 of whom 3 have died and 30 have disappeared and cannot be traced. As regards race, 96 were whites 6 negroes 16 half-castes and one a Chinese. Two were under 10 years old 10 were in the second decade, and in succeeding decades to the seventh the figures were 24 34 22 12 and 12 there were three patients over 70 years of age.

PEREIRA, P. C. R. As leprolinas Souza Aranzo—seu emprego—resultados em comparação com a reação de Mitsuda. [Tests with Souza Aranzo Leprolins compared with Reactions to Mitsuda's Lepromin.] *Mem Inst. Oswaldo Cruz* 1945 v 42, No. 1 217-21

The author has tested the leprolins of Professor de Souza Aranzo (see this *Bulletin* 1945 v 42, 1010-12) in two groups of lepers: one (28 in number) no longer harbouring the bacilli, the other (29) with bacilli, and has compared the results with those obtained from Mitsuda's lepromin. Positive reactions were evidenced by erythema of varying extent lasting for a few days and then gradually fading; rarely the erythema would appear late, some 8-12 days after injection of the antigen. Nodules varying in hardness with tissue reaction might also appear and occasionally there was suppuration with loss of tissue. In both groups three failed to give any reaction to the leprolina. In the first group the non-bacilliferous, 15 reacted to all the antigens and all 25 to antigen 4. In the second (bacilliferous) group one only reacted to all four antigens but all the 28 did so to antigen 4.

As regards Mitsuda's lepromin reaction this was tested in the nonbacilliferous group only. A table gives the results in each of the 28 patients. These may be summed up by saying that they were not in accord: a patient might give a positive to leprolin but negative to lepromin.

CHORINE, V. Traitement des lésions oculaires de la lèpre. [Treatment of the Ocular Lesions of Leprosy.] *Bull. Soc. Path. Exot.* 1945 v 38, No. 9/10 255-71 [21 refs.]

The treatment of the ocular complications of leprosy is discussed by Chorine. He points out that the eyes are frequently attacked by the disease but that the statistics collected by workers in different countries are contradictory. As examples of these he quotes the figures of ROGERS and MUIR (this *Bulletin* 25 v 22, 256) for India at 5 to 10 per cent, those of PICKERTON (*Arch. Ophthalmology* 1927 v 56, 42) in Hawaii and of JEANSELMÉ (this *Bulletin* 34 v 31, 754) in Indo-China at 100 per cent, those of FIDOREV and PAVLOV in Soviet Russia at 62 per cent. It is the opinion of most authorities that the longer the duration of the disease the commoner the ocular complications; that the nodular type more frequently causes involvement of the eyes than the neural type and that ocular complications of leprosy, including blindness, are much less frequent in warm than in temperate and cold climates.

The author advocates the use of sulphonamides parenterally and recommends the following solution:—

Acetamide	80 gm.
Septophix (sulphamylamide)	15 gm.
Distilled water	100 cc.

The injections are painful and are given around the circumference of the orbit. A preliminary injection of 4-5 cc. of 1-2 per cent. Stovaine is given into the orbit, and then the sulphonamide solution is injected into the anaesthetized area. Both eyes are treated simultaneously and one or two injections of 2 to 5 cc. are given into each orbit. Small doses are given at first to test the reaction of the patient and the injections are carried out once a week. The author reports remarkable improvements in the ocular complications as a result of this treatment.

HELMINTHIASIS

VISHNIEVSKAYA S M [Helminthological Examination of Sewage, Soil and Vegetables from the Bezludov Fields Manured with Sewage] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 4 14-18 [In Russian]

After quoting several Russian papers on the contamination of vegetables by helminth eggs the author records his examination of sewage water from the main and secondary canals used to irrigate the Bezludov fields and also of the sediment from these. He also examined washings from vegetables (tomatoes cucumbers and cabbages) grown on these fields. The observations were made in 1937 and 1938. Water samples were taken from the canals in bottles containing 48 litres these stood for two days before the sediment was examined by the author's modification of the method of LEIV, no reference to this method is given. Soil was taken from the surface of both irrigated and non-irrigated areas and also at a depth of 12 cm in samples of 200 to 250 gm. Vegetables were washed twice and both washings were centrifuged, the sediment after centrifugation being examined by the method of Lem.

The author found in the sewage water from the irrigation canals eggs of those species of helminths which have been found in the impure sewage water of the Kharkov district namely *Ascaris Trichuris Trichostrongylidae* and a cestode referred to as the dwarf-chain [some other Russian authors mean by this phrase *Hymenolepis nana* but unless the Latin name is given it is difficult to be sure what species is meant]. The majority of the eggs found were those of *Ascaris* and the following figures refer to these only. More eggs were found in 1 litre of the water from the main canals i.e. 22-40 per litre than in the same amount of water from the secondary canals i.e. 14-18 per litre. The author claims that this fact demonstrates the part played in dehelminthization by the canals. In the sediment from the main canals there were 3 to 10 eggs per gm and in the soil from the irrigated areas there were only 0.5 to 1 egg per gm. Thus the passage of the water along the canals at a speed of 22 cm per second removes the author claims 50 per cent of the eggs. The eggs of *Ascaris* found were not usually morphologically altered they were segmenting and, under favourable conditions most of them developed until infective larvae were formed in them. In the surface layer of the soil of the irrigated areas up to 70 per cent of the eggs of *Ascaris* were morphologically unchanged and 23 to 30 per cent of them were deformed. Isolated eggs when they were incubated, developed until they contained infective larvae. In ploughed soil of the irrigated areas the author found that from 65 per cent (in 1937) to 80 per cent. (in 1938) of the eggs were morphologically unchanged and these developed under favourable conditions until they contained infective larvae. In soil from the irrigated areas taken at a depth of 12 cm 55 per cent. of the eggs of *Ascaris* were morphologically unchanged but these did not develop under favourable conditions. In the soil from areas irrigated only before they were ploughed isolated eggs of *Ascaris* were found whose external appearance suggested that they were morphologically unchanged.

In sediments obtained after washing vegetables grown on the Bezludov fields the author found an average of 0.3 to 1 *Ascaris* egg per gm of sediment.

Isolated eggs of *Ascaris* were found on the vegetables grown on fields irrigated with sewage during the summer but no eggs of any helminth were found on vegetables grown on land irrigated with sewage water during the autumn or winter nor were any eggs found on vegetables from areas irrigated only before they were ploughed. [Cf VASILKOVA this Bulletin 1945 v 42, 569]

ALF S. [Contamination of Soil by the Eggs of Helminths by the Burial of Sewage.] *Med Parasit & Parasitic Dis* Moscow 1945 v 14 No 4 18-22. [20 refs.] [In Russian.]

After reviewing the literature on this subject the author records his observations on three shallow pits each with a capacity of 1 to 1.25 cubic metres in which faecal matter was buried. Two pits were in sandy soil and the third was in clay soil. The faeces contained 1 000 to 2 000 eggs per gm. and in 65 per cent. of these eggs active embryos developed under favourable laboratory conditions. These 65 per cent. were eggs of *Ascaris*. [The author does not state whether eggs of other species were found.] Samples of soil were taken with a soil borer around each pit at horizontal distances of 0.5, 1, 2 and 3 metres from the walls of the pits and at vertical depths from the bottoms of the pits of 0.5, 1.25 and 2.5 metres. These samples were taken in different directions at right angles to each other. Similar samples were taken from control plots distant 9 metres from pit no. 3 and 5 metres from pit no. 2. Each sample consisted of not less than 1 kgm. of soil. The eggs were recovered from the samples by a modification of the method of SPRENGER [no reference to this method is given] samples of 300 gm. of soil being thus examined. The results showed that there was no infection of the soil at horizontal distances of 0.5 to 3 metres from the walls of the pits or at vertical depths from the bottoms of the pits of 2.5 metres (i.e. 1 to 1.25 metres below the bottoms of the pits)

COCKBURN C. Ocular Cysticercosis Cellulosa. Report of a Case of Parasite in Vitreous. *Brit J Ophthalmol*. 1946, Feb v 30 No 2, 65-74 5 figs. (1 a coloured pl.).

COLL G. Hydatid Disease in Victoria. *Health Bull* Melbourne 1945 Jan-June Nos. 81-82, 2178-88 1 map Addendum I II & III pp 2189-92, 2 figs.

Hydatid disease was made notifiable in Victoria in 1926 and from then to the end of 1944 278 cases have been notified, 136 of them in the Western Health area 52 in the Central, and 43 in the North-western areas. That is 44.6 per cent. of notified cases have occurred in an area less than one-eighth of the State, with 4.4 per cent. of the State population it is practically certain that several escaped notification. The disease is in the main, restricted to the sheep-country and investigations at various abattoirs showed that from 28.7 to 71 per cent. of the sheep killed were infested with hydatids. Also of 24 dogs whose faeces were examined, 6 were passing adult *Echinococcus granulosus* these animals are commonly fed with uncooked offal from the slaughterhouses. Preventive measures are simple easily understood and easily applied, and a vigorous campaign is suggested the appointment of a committee to investigate the problem more deeply and the adoption of a publicity campaign the preparation of a wall-sheet showing the life history of the worm and the distribution of it to all schools exhibiting posters of similar design in abattoirs and at railway stations the wide distribution of leaflets and securing publicity by Press co-operation. The article mentions five other cestodes which may

infest dogs namely *T. hydatigena* (intermediate *Cysticercus tenuicollis*) *T. pisiformis* (*Cysticercus pisiformis*) *T. serialis* (*Coenurus serialis*) *T. ovis* (*Cysticercus ovis*) and *Dipylidium caninum* the last only infesting man

There are three addenda to the main article the first gives details of the investigation of dogs referred to above the other two are pamphlets of general information issued by the Medical Officer of Health and the Commission of Public Health. The last contains an excellent illustration of the small intestine of a dog heavily infested with the cestode. *H Harold Scott*

LASNIER, E P & CASSINELLI J F Diagnóstico de quiste hidático hialino (no roto) del pulmón mediante la inclusión de esputos. [Diagnosis of Unruptured Hydatid Cyst of the Lung by Examination of the Sputum.] *An Facul de Med Montevideo* 1945 v 30 No 12 903-45 14 text figs & 5 coloured figs on 1 pl. [32 refs.]

This long article pleads for examination of the sputum in patients with unruptured hydatid cyst of the lung. The authors show with illustrative photomicrographs and a coloured plate how by suitable staining (particularly by Best's haematin and carmine method) fragments of the cyst wall and minute cocco-bacillary bodies can be seen and diagnosis made. All this is gone into in much detail for which those interested must consult the original. *H Harold Scott*

HUNTER G W III & WORTH C B Variations in response to Filariform Larvae of *Ancylostoma caninum* in the Skin of Man. *J Parasitology* 1945 Dec. v 31 No 6 366-72 1 fig. [16 refs.]

Reports of the effects of penetration of the human skin by filariform larvae of *Ancylostoma caninum* have varied some record a transient papular dermatitis others deeper penetration and creeping eruption.

Two volunteers submitted themselves to infection on the right forearm with 1 000 or more filariform larvae of *A. caninum*. In both cases the immediate reaction was acutely inflammatory after that their reactions differed sufficiently to warrant separate description.

The first volunteer felt an itching and the area in 45 minutes became erythematous in 48 hours urticaria and papules were numerous and on the third day induration and tenderness and sulphadiazine was prescribed. Except for a slight rise of temperature less than 1°F on the 2nd and 3rd days there was no systemic disturbance. Subsequently at intervals increasing in length, there occurred attacks of transient urticaria. Biopsy revealed no parasites and the stools examined up to 180 days after infestation remained negative for ova. Leucocytes on the 3rd day totalled 9 900 per cmm. with eosinophiles 2 per cent. the highest eosinophilia was 9 per cent. among 8 850 leucocytes on the 85th day.

The second volunteer had an allergic history personal and familial. His immediate reaction to the application of the larvae was less intense on the 3rd day there was spreading inflammation with some superficial tenderness and papules were becoming vesicular. Burrows were visible on the 4th day. On the 7th there was deep induration of the forearm with aching pain and pitting oedema. Several times during the ensuing months there were renewed burrowings and localized swellings. But whereas with *A. brasiliense* the burrows are continuous with the site of entry of the larvae i.e. the larvae possess invasive properties against a poorly resistant host in the case of *A. caninum* there is local arrest and the larvae penetrate deeper and rise to the surface again at a distance (In the case of this experimental subject, some

7-8 in. from the site of entry) No ova were seen in the faeces at any time. In this volunteer the blood showed an eosinophilia of 28 per cent. on the 29th day in a total leucocyte count of 12,800 and of 15 per cent. on the 72nd day in a total of 12,000 after which the eosinophilia fell till the 181st day when the number rose to 1 072 (or 8 per cent. of a total leucocytosis of 13 400) from 522 (8 per cent. of 8 700) on the 120th day. It may be concluded that the human subject may vary constitutionally in his ability to arrest the invasion of a parasite which may be considered uniform within its species."

H Harold Scott,

MILWIDSKY H. The Surgical Complications of Ascariasis. *Acta Med. Orientalia (Palestine & Near East Med J)* 1945 Nov v 4 No. 11 370-84 28 refs

An account of the surgical complications of ascariasis illustrated by clinical details of 17 cases met with during six years surgical practice in Jerusalem. The most common complication is intestinal obstruction of which there are four varieties (1) mechanical, (2) spastic, (3) intussusception (4) volvulus. Five cases of mechanical obstruction all submitted to operation are recorded, two early cases in which the bowel was not opened, recovered and three with gangrenous intestine and peritonitis ended fatally after resection of intestine or ileostomy. Two cases are described in which the obstruction was due to ileus, in one of these the symptoms passed off after the administration of a spinal anaesthetic the other proved fatal after laparotomy and ileostomy. Intussusception and volvulus of the lower ileum occasionally occur. Three patients with the latter condition were operated on two of whom recovered, in one case after resection of 30 cm. of gangrenous gut and a temporary ileostomy. The mortality of this group of 10 cases was 50 per cent. cases which recovered being those in which the symptoms were of only one to two days duration.

Perforation of the bowel may take place through areas of inflammation or ulceration or through suture lines postoperatively. A case of persistent duodenal fistula after gastrectomy for duodenal ulcer is described, in which an *Ascaris* was eventually expelled through the fistula, with subsequent healing of the wound. Appendicitis may of course occur in infested subjects but cases are met with in which it appears to be directly due to the irritation caused by the parasite entering the appendix. Two such cases are cited, both of which recovered after appendicectomy.

Acute abdominal symptoms suggesting perforation of a duodenal ulcer may be caused, and two patients sent to hospital with this diagnosis were spared operation because in one case vomiting of some worms led to immediate improvement and in the other the fact that the patient had had two similar attacks during the previous 18 months for the first of which a laparotomy had been performed and only *Ascaris* infestation found, suggested the true diagnosis.

The bile and pancreatic ducts may be blocked by the worm migrating up the common bile duct, setting up cholangitis, cholecystitis and abscess of the liver all of which have been recorded. One of the author's cases arrived in hospital with a diagnosis of empyema of the gall-bladder but here too the vomiting of worms led to investigation and a correct diagnosis.

The differential diagnosis is discussed, but stress is laid on the imperative necessity of surgical intervention in the presence of acute abdominal symptoms and signs without waiting to see the effects of anthelmintic treatment. If a non-urgent abdominal operation has to be performed in an *Ascaris*-carrier pre-operative anthelmintic treatment is advisable.

W L. Harnett

ALEXANDER A E & TRIM A R. The Biological Activity of Phenolic Compounds. The Effect of Surface Active Substances upon the Penetration of Hexyl Resorcinol into *Ascaris lumbricoides* var *suis* *Proc Roy Soc Ser B* 1946 Feb 12, v 133 No 871 220-34 7 figs. [27 refs]

This paper must be read in original if it is to be fully appreciated.

The authors have devised a method of measuring quantitatively the effect of surface-active substances (sodium cholate sodium oleate and cetyl trimethyl ammonium bromide (C.T.A.B)) upon the penetration of hexylresorcinol into the nematode *Ascaris lumbricoides* parasitic in pigs. Parallel measurements have been carried out on the interfacial activity of solutions of the substances named against an inert mineral oil Nujol which is a pure high boiling paraffin. The work should be read in conjunction with the work of TRIM [this *Bulletin* 1944 v 41 596] ROGERS [*ibid* 1945 v 42 299] and the other authors quoted.

The action of all three substances was markedly similar and differed only in degree. When a fixed concentration of hexylresorcinol was used (0.025 per cent.) the soap in dilute solution accelerated the penetration of the drug the maximum acceleration being in the order sodium cholate < sodium oleate < C.T.A.B. High concentrations of the soaps however completely inhibited the penetration of hexylresorcinol. The soaps alone penetrated *Ascaris* only very slowly if at all. The soap and the hexylresorcinol molecules associate at an interface forming a labile complex of increased surface activity. The authors suggest that the biological activity of hexylresorcinol as measured by its rate of penetration of the cuticle of *Ascaris* is determined by the interfacial activity of this mixture and that when soap micelles are present the drug distributes itself between the micelles and any other interface present such as oil/water or *Ascaris*/water. Thus the maximum biological activity occurs at the critical concentration for micelle formation because this has maximum interfacial activity. At high soap concentrations the hexylresorcinol is held mainly by the soap micelles so that the biological activity is diminished ultimately it is diminished to zero because the soaps alone penetrate so extremely slowly. It has been possible to calculate from the data provided by the use of C.T.A.B./hexylresorcinol mixtures a theoretical curve for the biological activity of hexylresorcinol which agrees well with the results of experiment. The authors discuss the possible bearings of these results upon the anthelmintic activity of hexylresorcinol *in vivo* and also upon the action of drugs in general (e.g. the action of soaps together with phenols upon bacteria). The authors say that it may be quite feasible by adjustment of the relative amounts of drug and soap to control not only the intensity of biological activity but also the duration at any desired level up to the optimum. With drugs that have undesirable effects on the host this clearly is of great value.

HARRIS J S & SUMMERS W A. A Concentration Method for demonstrating *Microfilariae* in Blood. *Amer J Trop Med* 1945 Nov v 25 No 6 497-8

Four cc. of blood are taken from a vein and put into a tube containing 0.01 cc. of heparin solution (Liquemin Roche-Organon Inc. 1 ml. contains 10 mgm of purified heparin). 4 cc. of a 2 per cent. aqueous solution of saponin are added and mixed with the blood. When haemolysis is complete 6 cc. of the mixture are centrifuged for 10 minutes at 2,000 r.p.m. The supernatant fluid is drawn off leaving 0.1 cc. in the tube and this is spread on a slide and examined with a low power of the microscope if desired it can be stained afterwards.

The authors found this method superior to other concentration methods

AUGUSTINE D. L. & LHERISSON C. Studies on the Specificity of Intradermal Tests in the Diagnosis of Filariasis. *Amer J Hyg* 1946 Jan., v 43, No 1 38-40

Earlier work has suggested that intradermal tests done with antigen derived from *Dirofilaria immitis* of the dog has value for diagnosis of filariasis of man. The authors quote for example TALLAFERRO and HOFFMAN [this Bulletin 1931 v 28 214] FAIRLEY *ibid* 1932, v 29 427] DICKSON HUNTINGTON and EICHHOLD *ibid* 1944 v 41 303 MICHAEL (*ibid* 1956). But later work by WRIGHT and MURDOCK *ibid* 1954, and HUNTINGTON (*U.S. Nat. Med. Bull.* 1945 v 44 707) has given irregular and uncertain results. (See also ZARROW and RIFKIN below) Positive reactions ascribed to cross reaction with other nematodes especially intestinal species have been obtained in a large percentage of subjects who showed no clinical symptoms of filariasis and negative reactions ascribed to desensitization have been obtained in persons with acute severe symptoms of Bancroftian filariasis. The authors thought that this lack of specificity of the test might be due to sensitization by repeated exposures to species of filarid nematodes which do not infest man. Adult filarid nematodes are common in frogs lizards birds and mammals. These adults are markedly host specific and there are as many (or more) species of filarid nematodes as there are species of land vertebrates. It is very likely that filarid nematodes are the commonest helminth parasites of land vertebrates in regions where *Wuchereria bancrofti* is endemic.

The microfilarial larvae of these species however are less specific to their intermediate hosts. They can develop in many arthropods especially in mosquitoes. The life-histories of the species not parasitic in man have not yet been worked out. We can expect that they follow the usual pattern shown by *Dirofilaria immitis* of the dog. The microfilarial larvae of *D. immitis* can develop in more than 20 species of mosquitoes belonging to three genera. Its possible intermediate hosts include the usual vectors of *W. bancrofti* and of human malaria. Effective transportation to man of infective larvae of non-human filariae seems unquestionable and, in all probability this is a very frequent occurrence. It is also very probable that these microfilarial larvae which enter man are destroyed in his skin as the infective larvae of the hookworms of dogs and cats and the cercarial larvae of avian and rodent schistosomes are. But repeated infestations of man with these microfilarial larvae can be expected to provoke a potent immune reaction.

The authors therefore studied the specificity of skin tests done on rabbits with antigens made from filarid nematodes which are not parasitic in man namely *Dirofilaria immitis* of the dog *Setaria equina* of the horse *Listosomoides carini* of the cotton rat and *Agrofilaria columbigallinae* of the ground dove. Adult nematodes of these species were washed in running water and then given several baths of distilled water before they were dried over sulphuric acid in *vacuo* for 2 to 3 days. The dried nematodes were ground up and extracted for 3 days in physiological saline containing 1/10,000 merthiolate. After centrifugation the supernatant fluid was used as antigen. Dilutions were made on a dry weight basis and all tests were done on rabbits about 1 year old. Each of four rabbits was first immunized by subcutaneous injections, on eight occasions of 1 cc. of antigen diluted 1/1,000. On the tenth day after the last injection the intradermal tests were done by injection into a hairless region of the skin of the back of 0.2 cc. of antigen. Control tests were done with physiological saline containing merthiolate. All the antigens were also tested on normal rabbits. A reaction was considered positive when the diameter of the weal produced by the antigen exceeded that produced by the saline, by 3 mm. or more.

The four immunized rabbits were all positive to dilutions of 1 1 000 and 1 8 000 of each of the antigens. The tests done with the 1 1 000 dilutions were the first to appear and the last to fade they were more prominent and were positive 2 hours after the injections. By this time the weals caused by both specific and the non specific antigens varied from 30 millimeters in diameter to 50 by 70 millimeters for antigens in a dilution of 1 in 1 000. The largest weals were produced by the *D. immitis* antigen in a rabbit immunized with antigen from *V. columbigallinae* of the ground dove. This weal disappeared 18 hours after the injection as did also the weal produced by *Setaria equina* antigen the reaction produced by the specific antigen from *Litosomoides carinii* of the cottonrat was however still present at this time. Dilutions of 1 8 000 of the antigens produced milder reactions. After 2 hours the weals had a diameter of 15 to 30 mm and after 18 hours they were not conspicuous. The authors say there was no marked erythema or oedema except in all the tests with *Dirofilaria immitis* antigen in 1 in 1 000 dilution. Erythema and oedema were particularly prominent in the specific tests. All the reactions were inconspicuous or had disappeared after 18 to 30 hours. All the controls were negative. The duration of the sensitivity was not determined. The authors state that their experiments afford no direct evidence that infestations with the microfilarial larvae of filariids not parasitic in man can produce sensitivity in man but claim that their work shows clearly that the extracts of the filariid species used caused an immune response indicated by skin tests whether the antigen was specific or not. They therefore feel justified in supposing that (a) non human filariid nematodes can influence the serological reactions of man and (b) many hitherto unexplained false positive skin reactions to *D. immitis* antigen are due to responses produced by filariid nematodes which are not parasitic in man.

ZARROW M & RIFKIN H. Observations on the Specificity and Clinical Use of *Dirofilaria immitis* Antigen in the Diagnosis of Human Filariasis (*Wuchereria bancrofti*) *Amer J Med Sci* 1946 Jan. v 211 No 1 97-102 [18 refs]

Reviewing the literature on this subject the authors recall that KING [this *Bulletin* 1945 v 42 304] suggested the following three methods for the diagnosis of filariasis — (1) Microscopical demonstration of adult filariae by means of biopsy. The present authors agree that this method is certain but it takes time involves surgical removal of lymph nodes and perhaps the removal of several of these if the first ones removed are negative [see below] and it is not applicable to a field survey. (2) Demonstration of microfilariae in the peripheral blood. To this method the present authors object that nobody has yet demonstrated microfilariae in the blood of United States soldiers although they are abundantly present in the blood of natives of the areas investigated. In the present study moreover no microfilariae were found in the blood of the white subjects studied although repeated examinations were made both of fresh smears and by the concentration method of KNOTT [this *Bulletin* 1940 v 37 304]. (3) Demonstration of calcified filarial nematodes by Roentgen ray techniques [see O'CONNOR this *Bulletin* 1930 v 27 986]. The present authors state that it has not yet been shown that these techniques have any diagnostic value. They therefore decided to use a skin test.

A review is given of the literature up to 1944 on intradermal tests with antigen derived from *Dirofilaria immitis*, *Wuchereria bancrofti* and *Litosomoides carinii*. [The papers reviewed have been abstracted in this *Bulletin* see for example the summary of Recent Abstracts on Helminthiasis this *Bulletin*]

1945 v. 42, 670] The present authors tried to define — (1) a dilution of the antigen at which false intradermal positive reactions due to intestinal nematodes can be eliminated (2) the sensitivity of subjects suffering from filariasis to the antigen. It was possible also to compare the results of the intradermal tests done on some subjects with those of biopsies done on the same subjects. The antigen was made from *Dirofilaria immitis* by a modification of the method of HUNTINGTON reported personally to the authors by MICHAEL. These were then freed from blood by magnesium sulphate and acetone. The nematodes were then given several washings in acetone. The nematode antigen was prepared at a high time when the authors were in the tropics.

antigen can be eliminated. It was possible to do this by washing the antigen with blood to the antigen. Tests done on some subjects with those of the antigen. The antigen was made from *Dirrofilaria immitis* to the antigen. The antigen was reported personally to the antigen. These were freed from several dogs were removed from their hearts. They were then given several washes in running water overnight. They were then freed from blood clot and kept in running water at 37°C for 12 hours by which time they were thoroughly dry. The authors found that if this temperature was exceeded, the antigen lost potency. The dried nematodes were ground up and the powder was kept in the refrigerator as stock from which fresh antigenic extract was prepared each month. The extract was made by constantly stirred suspension of the powder in physiological saline which was constantly stirred for 2 hours at 37°C, and then filtered through a Seitz filter. Phenol was added to a concentration of 3 per cent. This 100 extract was diluted to 1 200 1 2 000 1 4 000 1 8 000 and 1 16 000. One contaminated batch of extract was re-filtered, and it was found that this process caused a loss of potency, a fact which was also reported by KING [loc. cit. above]. As a control, a fragment of the dog's heart was given the same treatment as the nematodes and diluted into the vial surface of the forearm. One arm received the intradermally into the 1 200 and 1 2 000 dilutions. The other received the control and the 1 200 and 1 2 000 dilutions, when positive reactions were dilutions. Results were read after 30 minutes, when positive reactions were at their height, and also after 24 hours. The authors took as a positive response a definite increase in size of the wheel as compared with the control together with erythema of 2 cm. diameter or more. *Enterobius vermicularis* with dilutions above 1 2 000 were 85 subjects free from clinical filariasis but infested with hookworms were 85 subjects free from clinical filariasis but infested with hookworms. No positive reactions with dilutions above 1 2 000 were observed with this man who had been infested with the nematode. This man was also positive to *Enterobius vermicularis* and *Ascaris lumbricoides*. The authors concluded that the cross reaction between *Enterobius vermicularis* and *Ascaris lumbricoides* was not a true cross reaction.

There were 68 subjects free from clinical filariasis but infected with hookworm and *Strongyloides stercoralis*. No positive reactions with dilutions above 1:2,000 were obtained in these subjects, with the exception of one who had herpes zoster as well as hookworm disease but this man was also positive to the control heart extract and a dilution of 1:4,000 does not give cross reactions. They conclude that a dilution of 1:4,000 obtained cross reactions with *D. immitis* antigen out. The presence of intestinal helminths Wright and Muxbrook (this Bulletin 1944 v 41: 1054) but they injected 0.1 cc. of the antigen, twice the amount used by the present authors.

The authors tested 91 subjects who showed clinical symptoms of filariasis. Of these 83 (91 per cent) gave positive reactions to at least one of the dilutions used. In a controlled group of 18 subjects who had no history of having served in an area in which filariasis is endemic but who showed no clinical signs or symptoms of filariasis 11 did not react to a 1:200 dilution of the antigen, 5 gave positive reactions to this dilution and 2 to a dilution of 1:2,000. At the higher titres none was positive. The authors conclude from their results that a positive reaction at a dilution of 1:4,000 or higher indicates the presence of filariasis. Using this as a basis for interpretation of their results they obtained a positive response in 78 per cent of their subjects. Comparison of biopsies of lymph nodes and skin tests done on the same persons showed that, in a group of 53 subjects 74 per cent. were positive to dilutions of 1:4,000 and 1:16,000 of the antigen, and that biopsies in 60 per cent. of these were positive but in several subjects more than one biopsy was

needed to find a positive gland. In this group 10 showed negative biopsies but positive intradermal tests and further biopsies might have been positive. In three subjects (6 per cent.) the biopsies were positive but the skin tests were negative a similar finding was also recorded by DICKSON HUNTINGTON and EICHHOLD (this Bulletin 1944 v 41 303).

In 55 soldiers all of whom had been exposed to filariasis and some of whom had enlarged lymph nodes but were otherwise free from symptoms positive intradermal reactions were obtained in 71 per cent to dilutions of 1:4000 and 1:16000 of the antigen.

Complete blood counts were done on all those who had filariasis. There were no marked deviations in the number of erythrocytes haemoglobin neutrophils or lymphocytes but 25 per cent of the subjects showed an increase in the number of white blood cells to 10000 per cmm. or slightly more. The eosinophils were increased to 34 per cent or more in the whole group of 91 men with clinical filariasis. When only those who gave positive skin tests to dilutions of 1:4000 or higher were considered it was found that 40 per cent had eosinophilia and 15 per cent of these harboured intestinal helminths.

LEEDE W E & JOSEY A I. The Early Diagnosis of Filariasis and certain Suggestions relative to Cause of Symptoms. *Ann Intern Med* 1945 Nov v 23 No 5 816-22

G Lapage

The authors studied 100 soldiers evacuated from various areas of the South West Pacific with filariasis. From only two of these men were microfilariae recovered. The diagnosis in the others rested on (1) a history of residence in an endemic area (2) a history of symptoms suggestive of early filariasis (3) the clinical findings (4) the results of skin tests with filarial antigens and (5) the subsequent clinical course of the condition. There is great variation in the initial symptoms of infections acquired in different localities but those from any one locality are constant. In general however after about one year's residence in an endemic zone an infected man experiences mild generalized aches and pains testicular pains and malaise and a more or less generalized lymphadenopathy and funiculitis develop. Lymphangitis is of diagnostic importance but is not always evident. In early cases microfilariae will only very rarely be found in the peripheral blood.

The immediate evacuation of early cases from the endemic zone will result at least in the temporary subsidence and possibly in the complete disappearance of the disease—it is yet too early to state which with certainty. The available evidence indicates that avoidance of reinfection or removal to a temperate climate or both result in diminution of the frequency and severity of the symptoms and in recession of the physical signs of the infection.

The causation of the symptoms and signs of early filariasis is difficult to explain on the basis of mechanical obstruction by the parasites such as leads to the irreversible changes seen in the later stages of the disease. An inflammatory or allergic tissue response appears a more probable explanation the sudden onset and evanescent nature of the initial symptoms and signs with an associated eosinophilia suggest an allergic basis for their occurrence.

GOODMAN A A WEINBERGER E M LIPPINCOTT S W MARBLE A. & WRIGHT W H. Studies of Filariasis in Soldiers evacuated from the South Pacific. *Ann Intern Med* 1945 Nov v 23 No 5 823-36 [18 refs.]

This is a report on the investigations made on soldiers repatriated to the United States from the small islands in the South Pacific as early cases of (1945)

Bancroftian filariasis. The clinical symptoms and signs of the disease were of minor severity and accord with those described by other American workers.

The authors examined the intracutaneous test (both direct and passive transfer) and the complement fixation test in their series of cases. For these purposes they used antigens prepared from *Dirofilaria immitis* and *Setaria equina* diluted 1/4000 and 1/8000 the antigen controls were similarly diluted preparations of dog and horse protein. In addition a series of non-filarial human controls was subjected to intradermal and complement fixation tests with the same antigens the results are set out in the text and in two tables. Some additional information is given of intracutaneous tests with antigens prepared from *Trichinella spiralis* *Leishmanoides carinii* and *Ascaris lumbricoides* in varying dilutions and also to Frei's antigen in view of the importance of differentiating inguinal gland enlargements due to lymphogranuloma inguinale and to filariasis. The undesirability of using antigens in stronger solution than 1/8000 for intracutaneous tests is indicated, and there is a comment on the disappointing degree of specificity of both the intradermal and the complement fixation tests, and their correlation in diagnosis.

The authors conclude with the following summary —

1 Clinical findings and results of intracutaneous and complement fixation tests in 145 soldiers evacuated from the South Pacific Area because of suspected bancroftian filariasis, are presented.

" 2 Signs and symptoms suggestive of filariasis including lymphadenopathy lymphangitis scrotal edema funiculitis orchitis and varicocele, arose on the average after about 13 months residence in an endemic area.

" 3 The symptoms were, in general, mild and only six patients experienced bouts of acute lymphangitis during the period of study in the United States. No case of elephantiasis occurred. No case of chyluria was encountered.

" 4 Microfilariae were demonstrated in the blood on one occasion in each of four patients (in two of these at overseas hospitals)

" 5 In 47 patients eosinophilia of 4 per cent. or greater was found in eight patients the percentage was 10 or greater

6 Microscopic examination of excised lymph nodes in 19 cases showed only a non-specific inflammatory response ("reactive lymph node"). No adult worms or remains of worms were seen.

" 7 In four of 29 cases roentgenograms of the scrotum showed tiny areas of calcification. However it is not possible to state that such calcification was due to the presence of *W. bancrofti*.

" 8 Direct intracutaneous tests using antigens of *Dirofilaria immitis* and *Setaria equina* in 1/8000 dilution gave positive responses in 84 per cent. of cases as compared with 6 per cent. in a series of 106 control subjects. Of 75 patients tested with 1/200 dilution of *Leishmanoides carinii* 77 per cent. gave positive reactions.

9 In passive transfer tests positive responses were obtained to either or both *D. immitis* or *S. equina* antigen in 1/8,000 dilution in 29 per cent. of cases. Of 50 patients tested with a 1/200 dilution of *L. carinii* 46 per cent gave positive reactions.

10 Positive complement fixation tests were found in 95 or 66 per cent., of 143 patients studied. However the complement fixation technique used cannot be considered wholly specific since 16 to 25 per cent. of normal control subjects gave positive tests. It is believed that improvements being effected in the technique of the test will reduce the number of non-specific reactions. There was agreement between the results of the complement fixation tests and the direct intracutaneous tests with *S. equina* and *D. immitis* in 68 and 71 per cent. of patients respectively

11 No specific treatment was given. Therapy included a liberal diet, reconditioning by means of gradually increasing activity and psychotherapy to allay fears as to possible future complications of the disease. The outlook for the men is considered good because of the relatively short residence in the endemic area and the slight degree of infection.

A R D Adams

WEBSTER E H. Filariasis among White Immigrants in Samoa. *U.S. Nav. Med. Bull.* 1946 Feb v 46 No 2 186-92, 1 graph.

These observations were made on 80 white men and women civilian immigrants in Samoa who had lived there for at least 10 years. The examination consisted largely of questions regarding their histories and circumstances of life in Samoa, signs and symptoms of filariasis and the dates of their appearance. Little importance was attached to the examination of blood films for microfilariae except in special cases and physical examination was limited to cases of elephantiasis. Eleven had also lived in other endemic areas of filariasis but most had not been exposed to infection until they were nearly 30 years of age and had been exposed afterwards for over 25 years.

Symptoms and signs of filariasis were present in 27 of 54 men and 11 of 26 women. The incidence of filariasis was related to the degree or amount of exposure and therefore to occupation [the numbers are small]. Figures are given for the average time of appearance of the initial symptoms in males and females and the parts of the body affected. Many gave a history of several attacks of lymphangitis and fever in a year. There were 15 persons with elephantiasis. Their ages ranged from 41 (very slight) to 78 (severe) average 64 years and the average duration of exposure to infection was 35 years. The relation to the number of acute attacks is shown in the following table —

Recurrence of acute symptoms

Number of recurrences	1-10	11-20	21-40	41-60	over 60
Without elephantiasis	17	2	2	2	0
With elephantiasis	0	5	2	4	4

There was only one case of severe elephantiasis in a trader aged 78 with both arms and both legs affected.

SCHLOSSER, R. J. Observations on the Incidences of *Wuchereria bancrofti* Larvae in the Native Population of the Solomon Islands Area. *Amer J Trop Med* 1945 Nov v 25 No 6 493-5

Thick blood films taken at various times by day or night from some hundreds of natives of three of the Solomon Islands (Guadalcanal, Malaita and San Christoval) from natives of the Gilbert Islands and of the Fiji Islands were examined for microfilariae of *Wuchereria bancrofti*. The parasites were found in about 20 per cent. Other observations showed that there was a definite periodicity the night blood containing far more microfilariae than the day blood, the difference in numbers being more marked in natives of the Solomon Islands than in those of the Gilbert Islands.

Some feeding experiments were made in the Gilbert Islands with *Aedes punctulatus punctulatus* and *Aedes punctulatus farauti*. The microfilariae did not survive for more than 36 hours in the former species and in one only out of 24 of the latter did microfilariae live for more than four days. The author states

that BYRD and St. AMANT have demonstrated that in the Solomon Islands the microfilariae will readily develop to the infective stage in *Aedes punctulatus farauti*.

DANGLADE, J. H. & FITZGERALD P. J. Asymptomatic Microfilariaemia in the Caribbean Area. *U.S. Nav. Med. Bull.* 1946 Feb. v 48 No 2 193-201 2 figs. [22 refs.]

Microfilariae of *Wuchereria bancrofti* were found in the night blood of 9 negroes of St. Croix Virgin Islands who gave no history of having had signs or symptoms of filariasis and in whom none could be found on physical examination. In blood taken between 11 and 12 o'clock at night no microfilariae were found in fresh preparations they were seen in stained thin films in 5 and in stained thick films in 7 by the use of a modification of a concentration method (LAWRY) in which 2 cc. of blood were mixed with 10 cc. of 2 per cent. formalin and centrifuged at 2,000 r.p.m. for 5 minutes, and the stained sediment examined, the microfilariae were found in the remaining two patients. [See also O COCHRAN and BEATTY this Bulletin 1938 v 35 761]

BASTONE, R. N. MERRIN A Few Facts about Filariasis for Folks who fear that Filaria-Infected Fellows will fetch Filariae from the Front. *Hawaii Med. J.* 1945 Nov-Dec. v 5 No 2, 69-71

The author's summary expresses completely the contents of the paper —

1. Our cases suffer *mermin* an allergic response to worm protein but do not produce microfilariae in the blood at least in demonstrable numbers.

2. It takes years of intensive exposure to develop a good micro-filaria producer. Our men have not had that exposure.

"3. In most of our men the worms will probably all die before the man is decimated — if some should survive they will not be in large numbers nor have sufficient life-expectancy to produce secondary micro-filaria-carriers.

"4. Transmission in the homeland will be inefficient also because of the average citizen's aversion to mosquitoes and the extreme paucity of the reservoirs of micro-filariae

"5. Filicidal drugs are known. They can be used if needed, to control transmission. At present they are still in the experimental stage and they appear to aggravate the symptoms of *mermin*."

SEN, K. & GHOSE, N. Ocular Gnathostomiasis. *Brit. J. Ophthalm.* 1945 Dec. v 29 No 12 618-26 1 text fig & 1 pl.

A case of *Gnathostoma spinigerum* in the anterior chamber of the eye is described by Sen and Ghose. This is probably the first recorded case of this worm in a human eye. The onset occurred with a dull aching pain on the left side of the nose extending to the left frontal and temporal regions. Swelling of the face then occurred, extending from the angle of the mouth to the roots of the hair and was followed by orbital cellulitis, vitreous and retinal haemorrhages. Later the patient had two attacks of iritis with the development of grey nodules on the iris which completely disappeared, leaving grey depressions. This was followed by two more attacks of iritis with the development of a single pigmented nodule on the iris in each attack. The pigmented nodule completely disappeared, leaving no mark after the first attack. In the second attack, which was the more severe the pigmented nodule was seen to be the worm. The worm was removed at operation and the eye made an uneventful recovery though optic atrophy developed. The habit of the *Gnathostoma* of burrowing through the tissues and migrating from place to place explained all

the signs especially the inflammation which, before subsiding in one place appeared in a contiguous place in quick succession.

The size of the worm was as follows —Length 3.5 mm maximum width 0.41 mm level of maximum width 0.41 mm from the anterior end width of the head 0.25 mm the number of rows of spines on the head bulb was 4. The authors are of the opinion that if the infection took place through the gastrointestinal tract it must have been through swallowing infected *Cyclops* in drinking water. It was not clear how the worm came to the side of the nose from the stomach without causing any sign or symptom. The probable area of its entry into the eyeball from the orbit could be seen as a scar just below the macula.

WHITTIER L. EINHORN N H & MILLER J F *Trichuriasis in Children. A Clinical Survey of Fifty Cases and Reports of Three Cases with Heavy Infection and Striking Clinical Symptoms. Amer J Dis Children* 1945 Nov-Dec. v 70 No 5 289-92.

The authors have analysed the symptoms and treatment of 50 children infested with *Trichuris trichiura* and show that the symptoms may be serious and severe even fatal cases have been reported though none of those under the authors' observation died. All 50 were admitted to the paediatric ward of the Gorgas Hospital Ancon during the years 1941-43. Three came from well-sanitised areas of the Canal Zone 22 from overcrowded districts with fair sanitation provided but not fully utilized and 25 from semi-rural communities living amid primitive conditions. The ages of the patients ranged between 12 months and 12 years 28 were under 7 years old 23 were boys 22 were girls. The common complaints were abdominal distress or pain in 9 diarrhoea in 7 blood in the stools in 5 vomiting in 3 but many of the patients were in hospital for other diseases than mere trichuriasis so evaluation of these complaints is not possible. In only one was the pain suggestive of appendicitis whereas SWARTZWELDER had recorded 16 out of 81 in whom the abdominal pain was localized in the right lower quadrant [see this *Bulletin* 1940 v 37 660]. The authors found that the typical history was of diarrhoea of 1 to 3 months' duration latterly stools streaked with blood recurrent pain in the abdomen with tenesmus loss of weight and rectal prolapse the worms were often seen by the parents in the wall of the prolapsed bowel. Twelve of the patients had eosinophilia from 5 to 14 per cent. haemoglobin 60-70 per cent. and red corpuscles 3½-4 million per cmm. values which compared favourably with those observed in well children in Panama. In the three cases detailed, leucocytosis to 13 500 was present in one only in the others the count was normal and in none of the three was there any eosinophilia in two no eosinophiles are mentioned, only polymorphonuclears and lymphocytes and in the third the differential count [was] within normal limits.

The best treatment in the authors' view is hexylresorcinol crystals *per os* combined with retention enemata of hexylresorcinol 1:1 000 but in each of the three cases detailed it will be observed that though general improvement took place the patient on discharge from hospital still had ova of *Trichuris* in the stools

H Harold Scott

NEGHEM R. A. *Epidemiologia de la Triquinosis [Epidemiology of Trichiniasis.] Biológica* Santiago 1944 Sept. No 1 127-40 1 graph. [11 refs.] English summary

The author analyses some of the causes which determine the endemic state of Trichinosis in Chile and indicates frequency attained in rats hogs and in man

"Trichinosis in rats has been stated in Santiago (5%) and in Concepción (7.8%) trichinosis of pigs in the slaughterhouses all over the country in quantities which range from 0.1% in the towns of the North (Antofagasta) up to 6% in some small towns of the South (Quirihue)

In man several *Trichinosis* epidemics have been discovered during the last 50 years in different towns of Central and South Chile. The author has collected from 1940 to 1943 148 cases of Trichinosis diagnosed mostly by means of Bachman's intradermic reaction. The inquiries on sub-clinical Trichinosis carried out in 294 corpses of the Santiago hospitals by Martink as well as by the author showed a 12.5% infestation with *Trichinella spiralis*. Investigations carried out with Bachman's intradermic reaction in healthy persons showed delayed positive reactions in 5 out of 96 tested individuals (5.2%)

GOULD S. E. An Effective Method for the Control of Trichinosis in the United States. *J Amer Med. Ass* 1945 Dec. 29 v 129 No 18 1251-4 3 figs. [Refs. in footnotes.]

This is a useful review of the incidence and control of trichiniasis in the United States in which the author decides that the best and most economical method of controlling this disease in man and hogs is the processing of pork products. No new facts are recorded in the review but some of the facts given are in themselves interesting

Recent surveys of the incidence of *Trichinella spiralis* in human post mortem material in the United States have shown that the average incidence is 16 per cent. (see GOULD S. E. Trichinosis, 1945 Springfield, Ill. Charles C. Thomas) More thorough methods of examination have shown that the incidence in some areas may be as high as 96 per cent. (see EVANS *J Infect Dis* 1938 v 63 337)

The incidence of *Trichinella spiralis* in hogs in the United States during the last 50 years has not varied from 1.5 per cent. It is possible that each American during life may eat nearly 200 meals of pork infested with *Trichinella*, and it is therefore not surprising that 16 per cent of human diaphragms examined at autopsy contain larvae of *Trichinella*. The morbidity rate from trichiniasis is not definitely known because many infestations are subclinical and, even when symptoms occur they may not be correctly diagnosed but the mortality rate of cases clinically diagnosed is 5 to 6 per cent.

Discussing methods of control, the author says that little progress has been made during the last 50 years in the control of trichiniasis. About 70 per cent. of the pork products made in the United States are made in plants under Government supervision they carry the label "U.S. inspected and passed" but this label on non-processed pork products does not mean that these are free from viable *Trichinella* larvae. Meat packing plants which are under Government inspection must observe Federal regulations for processing pork of the kind usually eaten uncooked and this pork may be expected to be free from viable larvae. But pork prepared in other plants under Federal inspection and all pork not under Federal inspection may contain living *Trichinella* larvae. Sausages are especially dangerous because they are often eaten raw or insufficiently cooked. Because only about 70 per cent. of pork is produced under Federal inspection and because even in these plants it is only the processed pork which can be expected to be free from living *Trichinella* larvae most of the American pork which goes to the kitchen may contain living larvae. Further pork may be put in other foods (meat loaf frankfurters etc.) or bought in shops and, if this is eaten uncooked, it is dangerous. During

recent years there have been numerous lawsuits against packers because of illness or death, with remarkably high awards for the plaintiffs

The incidence in American hogs of 1.5 per cent. is in sharp contrast to the incidence in hogs in Canada (0.57 per cent.) Poland (0.05 per cent.) Germany (0.001 per cent.) and Copenhagen (0.00075 per cent.)

The following methods of control are discussed by the author (1) Destruction of rats. The author considers that pigs rarely eat rats and that although it is wise to exterminate rats they play only a small part in spreading trichiniasis

(2) Education of the public. This is advisable but is by itself of little value.

(3) Skin testing of hogs. The author quotes the opinion of B. SCHWARTZ (*Ann Rep Smithsonian Inst* 1939 413) that this is not a reliable method of determining the incidence in hogs. [But see the flocculation slide test of SULLSSENGUTH and KLINE this *Bulletin* 1946 v 43 360 and the opinion of these authors that their method is a valuable means of determining the incidence in hogs.]

(4) Microscopic inspection of pork. This has proved quite effective in some countries and has been used extensively in Germany. The author concludes that systematic enforcement of it almost eradicated trichiniasis from Germany. Other countries which require microscopic inspection of pork are Denmark, Sweden, France, Argentina and Chile. The United States required it to be done from 1891 till 1906 but only for pork intended for export. Bismarck in 1880 and 1883 prohibited the import by Germany of American pork and even when in 1891 microscopic inspection was instituted in the United States Germany required its reinspection and in 1898 refused to accept the United States certificate that the pork was free from *Trichinella*. [For another discussion of this aspect of meat inspection for Trichiniasis in America see also SCHWARTZ *J Amer Vet Med Ass* 1941 v 98 458] Microscopic inspection was abandoned by the United States in 1906. It has never been applied to pork eaten in the United States. It takes much time although phototrichinoscopes have made it possible to throw on a screen images of several samples of meat from each hog. Further this method may miss infestations when the larvae are young and are not encysted or are in uncalcified cysts because then it is difficult to see them and most hogs in the United States are slaughtered when they are less than a year old, i.e. when any larvae in them are in this condition. Also portions of pork may be examined which do not contain larvae although they are present elsewhere in the hog examined. Microscopic inspection may also give the public a false sense of security.

(5) Elimination of garbage and offal from hog feed and the cooking of garbage given to hogs. Cooked garbage is given to hogs in Canada, England, the Hawaiian Islands and the American States of Kentucky, Oregon and New York. It has been repeatedly advocated and would greatly decrease the incidence of *Trichinella* in hogs. Yet 0.9 per cent. of grain fed hogs are trichinized (see SCHWARTZ *J Amer Vet Med Ass* 1938 v 92, 317). This method could not be enforced except upon large breeders. In the American States named above the difficulties of enforcing it have made this method ineffective and in Oregon State people can feed hogs on garbage from their own houses. A large corps of inspectors and others would be needed to enforce this method.

(6) Processing. This measure includes freezing, cooking, smoking, curing etc. Larvae of *Trichinella* are killed by a temperature of 55°C but Federal regulations require that all parts of meat heated to kill these larvae shall be heated to 58.33°C (137°F). Freezing is chiefly used for processing pork. AUGUSTINE (*Amer J Hyg* 1933 v 17 697) showed that raw pork in commercial quantities can be freed from *Trichinella* larvae by a temperature of -35°C (-31°F). BLAIR and LANG (*J Infect Dis* 1934 v 55 95) found that freezing

at $-17^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) for 72 hours killed these larvae. Most of the "deep-freeze" cabinets used in homes give temperatures varying from 0 to 5°F and these can be maintained. This method would cost relatively little and would by killing larvae in any scraps of pork which reach hogs quickly reduce the incidence of trichinosis in hogs and would check its spread in man. *G Lapage.*

PÉREZ ARA A. & PÉREZ VIGUERAS I. Sur un nouveau nématode découvert dans la paupière de l'homme [On a New Nematode discovered in the Human Eyelid.] *Bull Soc Path. Exot* 1941 v 34 Nos. 4/7 104-7 2 figs.

This note records the removal from the lower eyelid of a Cuban aged 27 of fragments of two unidentified nematodes. About a week before he was seen the patient noticed a very small swelling in his right lower eyelid, which caused him no inconvenience. This swelling appeared to be a non-inflammatory slight thickening about the size of a small pea in the external third of the lower eyelid 1 mm from its free border. It was elastic to the touch and not painful on pressure. The adjacent conjunctiva was normal. When it was removed, the swelling was yellowish white with yellowish white granular contents. From it emerged spontaneously two filiform motile organisms tapering at both ends and resembling worms. These were fixed and examination showed that they were the caudal ends of two female nematode worms both of which were gravid. The anterior ends were not found. One fragment was 7 mm. long, the other 3 mm. The maximum diameter of each was 220 microns. The cuticle was relatively thick with transverse striations only at the caudal extremity although longitudinal striation was evident throughout the length of the fragments and especially on the ventral and lateral surfaces. There were no cuticular spines papillae or lateral alae. The anus was 200 microns from the caudal extremity and the vulva 837 microns from it. The vulval opening was transverse to the long axis of the body. The vagina was cylindrical and relatively large. The uterus contained shelled eggs elliptical in form smooth and easily seen. They measured 20 to 23 microns long by 12.6 to 13.5 microns broad. Some were segmented and some contained embryos. There was no ovjector. No trace of the oesophagus was found in the larger fragment 7 mm long so that the authors concluded that a good part of the anterior end was lacking. The eggs were the authors remark, considerably smaller than those of nematodes parasitic in man. They could not identify the nematodes.

DEFICIENCY DISEASES

SEN P C in collaboration with S C SEAL. Types of Oedema Cases seen in a Rural Area in Bengal. *J Indian Med Ass* 1945 Dec v 15 No 3 67-74 & 76 1 sketch map & 1 graph.

Nine cases were studied in considerable detail. There is a general tendency to regard oedema, especially oedema of the extremities and occurring in Bengal as epidemic dropy. The plan of investigation included—(a) General Case Schedule for information of identity history dietetic habits etc. (b) Nutritional Assessment Card with information obtained from physical examination of the patient. (c) Economic Survey Schedule for information as to income, expenditure economic status etc. (d) Diet Survey Schedule, for recording the quantities of various foods taken during a period of 7 days.

Six families were involved. The information mentioned under each of the above is presented in a series of Tables and the upshot was that five of the nine

cases were diagnosed as epidemic dropsy (in two families which used mustard oil containing Argemone oil) three were associated with nutritional deficiencies notably of vitamins A B₁ B₂ and C the ninth was a case of oedema with anaemia secondary to chronic dysentery The last four were infested also with ankylostomes which may have played a part in causing the oedema

HUGHES W Fatty Liver and Malignant Malnutrition. [Correspondence.]
Lancet 1945 Dec. 29 861-2.

In this letter Hughes draws attention to the part played by ariboflavinosis in the aetiology of malignant malnutrition with fatty liver He shows that ariboflavinosis is the most outstanding feature in the epidemiological and clinical pattern of kwashiorkor—there is a high incidence of ariboflavinosis in the adult population of Southern Nigeria the lesions of kwashiorkor are similar to those of ariboflavinosis and both have parakeratosis as the underlying epithelial histological process the mode of death in kwashiorkor may be sudden with coma, as in dogs suffering from ariboflavinosis SEBRELL [*Bulletin of Hygiene* 1930 v 5 374] has shown that deprivation of riboflavin in dogs may lead to fatty liver and death in coma Riboflavin however will not bring about recovery in the late stages and Hughes suggests that deficiencies in other vitamins may be present

Deficiency of riboflavin may be prevented by the use of milk or yeast in the diet. Milk is expensive and in the tsetse belt of Africa may be impossible to obtain but food yeast at a cost of less than a farthing a day would prevent the condition

REINGOLD I M & WEBB F R Sudden Death following Intravenous Injection of Thiamine Hydrochloride *J Amer Med Ass* 1946 Feb 23 v 130 No 8 491-2. [13 refs]

1 Sudden death followed an intravenous injection of a solution of thiamine hydrochloride.

2 The patient had been given four injections at frequent intervals prior to death. Following the last injection she complained of a generalized burning perspired profusely became dyspneic and cyanotic and soon died.

3 The death is considered an example of an anaphylactic shock, the thiamine hydrochloride being the anaphylactogen

4 Pathologically, the anaphylaxis probably manifested itself in constriction of the smooth muscles of the pulmonary arteries and bronchioles resulting in pulmonary engorgement and right heart dilatation and failure and in mild pulmonary emphysema respectively In addition small foci of polymorphonuclear leukocytes and round cells were seen in thickened septums of pulmonary alveoli. Foci of pigmented macrophages probably indicated that previous hemorrhages had occurred following an anaphylactizing injection.

HAEMATOLOGY

MURPHY R C Jr & SHAPIRO S The Pathology of Sickle Cell Disease *Intern Med* 1945 Sept. v 23 No 3 376-97 6 figs. [42 refs.]

In sickle cell disease the sickling is an inherent property of the red cell and is determined by the ratio of oxyhaemoglobin to reduced haemoglobin within the cell. It appears that each cell has a specific threshold or level of haemoglobin in the reduced form at which it will sickle. Once this threshold is

to hospital. He complained of pain on swallowing but there was no dyspnoea, no headache vomiting or diarrhoea. Prior to admission he had been given $\frac{1}{2}$ grain morphine sulphate 500 cc. of whole blood and 1 000 cc. of saline intravenously (also for some unexplained reason 2 gm. sodium bicarb. per os every 4 hours). When he was admitted the site of the bite was anaesthetic and his speech was "thickened" from swelling of the lips face and tongue. The face scalp and neck were brawny with non-pitting swelling; there was no respiratory obstruction, no nervous symptoms were present and the reflexes were normal. Blood examination gave red cells 3,240 000 and white cells 8 000 per cmm (87 per cent. polymorphonuclears). Ten cc. (one unit) of Brazilian antivenene was given intramuscularly 9 $\frac{1}{2}$ hours after reception of the injury. [Nothing is said of the constitution of this antivenene but the statement is made that it was known not to be specific for the venom of this snake.] In another 8 $\frac{1}{2}$ hours the oedema had involved the right shoulder and upper part of the chest in front and there was some dyspnoea from swelling of the tissues. Fourteen hours later still, i.e. 32 hours after the bite the swelling had spread all over the front of the chest being more marked on the right side. The patient was coughing up some mucopurulent sputum. Penicillin was started [dose not stated] to guard against secondary infection. In two days there was no further swelling nor any more dyspnoea but the swelling had become ecchymotic. The pulse-rate had kept about normal 70-80 per minute and the blood pressure unaltered. On the fourth day the skin over the swollen area was purple to blue-black. Another blood count gave leucocytes 4 600 per cmm., with differential percentages normal. During the succeeding week the swelling gradually subsided, and a fortnight after his admission the patient returned to duty the only residual symptom being slight swelling of the left cheek and upper eyelid.

Five of the eight patients received the Brazilian antivenene at intervals ranging from one to ten hours after infliction of the bite and the author remarks "such a small number of cases affords no true index of the value of the Brazilian antivenom" however it is the writer's opinion that those who received the antivenom late or not at all, recovered as well as those who received it early. [In view of the specificity of most snake antivenenes this is not surprising.]

WYON P. H. Four Cases of Russell's Viper Bite. *Brit Med J* 1945
Dec. 29 919-20 1 fig

Four cases of snake-bite incurred in Central Burma are described, one of which was fatal. The snakes responsible were identified as Russell's vipers apparently by the author. The identity of the largest which measured 4 ft. 6 in. was confirmed by the local district laboratory.

The routine treatment is described in detail. A tight tourniquet was applied to the limb above the bite and antivenene was at once given intravenously. The patient was anaesthetized with pentothal, and incisions were made "in the line of the bite" down to but not through the deep fascia unless the fascia had been penetrated by the bite. The cases were then treated by venesection from the affected limb and by retaining a venous tourniquet for as long as 18 hours. By releasing the tight tourniquet regularly intermittent venesection was achieved. Later the patient was transfused if necessary.

The author discusses certain clinical aspects of snakebite and its treatment. Most unfortunately no autopsy was carried out in the fatal case. This patient was given antivenene soon after being bitten on the right wrist and was

first seen by the surgeon about 8½ hours later. He died as far as can be made out from the case history about 29 hours after the bite.

DERMATOLOGY AND FUNGUS DISEASES

MOURÃO B M O papel do estreptococo no pénfigo foliaceo (fogo selvagem)
 Estudo clinico-bacteriologico [The Part played by Streptococci in Pemphigus foliaceus (Wild Fire) Clinical and Bacteriological Study] Mem Inst Butantan 1943 v 17 141-285 28 figs. & 8 graphs [83 refs.]
 English summary

Though this monograph first saw the light nearly three years ago it may be regarded as up to date since no work has been done on the subject in the interval. It may be looked upon as a complete monograph on *pemphigus foliaceus* and its association and possible aetiological connexion with streptococci. It comprises more than this for it includes a brief review of the rôle of streptococci in dermatology.

The whole is divided into twelve chapters of which the first is introductory and the last two sum up the rest. The introductory chapter tells of the investigations of LINDENBURG on *pemphigus foliaceus* and Dühring's *dermatitis herpetiformis* and his conclusions that the former was an infective disease due to a virus which circulated in the blood and was transmissible to laboratory animals notably rabbits and guinea-pigs. Others however and the present author among them were unable to confirm this and took up the study afresh, this time from a bacteriological angle to investigate methodically the pyogenic bacteria in pemphigus and dermatoses generally, bullous or otherwise. The second chapter reviews previous published work on streptococci in dermatoses of the pemphigus group and concludes that the organisms are not important primarily but are ready secondary invaders of the bullae. Chapter III states the plan proposed, which includes skin culture, blood culture, bacterial study of material taken ante- and post mortem, identification of the types isolated, their toxins and their pathogenicity for laboratory animals. Chapter IV speaks of the material for study obtained from 160 cases of this disease including 87 of the generalized chronic form, 36 in the primary bullous stage, 15 of general dermatosis, the dystrophic form, 12 with localized dermatosis or *formes frustes*, 8 in the regressive stage and 2 healed cases, one with cutaneous sequelae and one without. In chapter V details of the results are given. Skin cultures were made from 55 patients, among them 21 in the generalized chronic stage and 16 in the invasion stage; cultivations were tried from the bullae, from crusts and from fluid obtained by puncturing the bases of bullae. Of 53 cases (2 had recovered) 43 had streptococci in the lesions. Not in a single one of those in the primary bulla stage with clear fluid, were streptococci found, but in all those with purulent contents or those crusted over without exception. In the latter there might also be *Staph albus*, *Staph aureus*, *Bact coli* and diphtheroids. In the *formes frustes* streptococci were isolated from 25% the haemolytic form in 12.5% and inert streptococci in 12.5% [but only 8 cases of this form were examined by skin culture so these figures would imply that haemolytic streptococci were found in one case only and the same as regards non-haemolytic streptococci. To state this as 12.5 per cent. of cases tends to mislead.]

Of four cases of Dühring's *dermatitis herpetiformis* two gave a growth of haemolytic streptococci, one of them associated with *Staph albus*, a third gave *Staph aureus* only. Chapter VI tells of the results of haemoculture. This was done in 150 cases and streptococci were grown from 19 (12.6 per cent.)

the parasite and blood culture may prove of value in diagnosis but it necessitates some delay. The cutaneous sensitivity test with "histoplasma" is as yet of undetermined diagnostic value. The prognosis is almost uniformly unfavourable.

NIÑO F. L. Granuloma paracoccidioidico. Estudio de una nueva observación en la República Argentina. (Nota previa.) [Paracoccidioidal granuloma. Study of a New Case in the Argentine Republic. Preliminary Note.] *Rev Soc Med Argentina* 1945 July 30 v 59 No. 562, 830-34 7 figs.

This is a report of a new case of paracoccidioidal granuloma in which the infection appears to have been contracted in Buenos Aires. The patient, a man aged 44 was a trader in charcoal and maize materials from which, the author considers the infecting fungus may have been derived. The lesions were situated in the mouth and there was an associated mass of enlarged and suppurating glands, the size of a pigeon's egg in the neck. The lungs were also involved and the parasite was found in the sputum and in material aspirated from the bronchi with the aid of the bronchoscope. The diagnosis was made by microscopical examination of the sputum, tissue obtained by biopsy and pus from lymphatic glands and was confirmed by cultivation of the fungus and by the results of the inoculation of morbid material into guinea-pigs.

TROPICAL OPHTHALMOLOGY

- i. DANSEY BROWNING G. C. & RICH, W. M. Ocular Signs in the Prisoner of War returned from the Far East. *Brit Med J* 1946 Jan. 5 20-21 [11 refs.]
- ii. RIDLEY H. Ocular Manifestations of Malnutrition in released Prisoners of War from Thailand. *Brit. J Ophthalmology* 1945 Dec. v 29 No. 12, 613-18.
- iii. GARLAND H. G. Ocular Signs in the Prisoner of War from the Far East. [Correspondence.] *Brit Med J* 1946 Jan. 26 143.
- iv. CHURCHILL, M. H. Dietary Deficiency Diseases among Prisoners of War. *J Roy Army Med Corps* 1945 Dec. v 85 No. 6 294-8.

i. The ocular signs of malnutrition in prisoners of war returned from the Far East are discussed by DANSEY BROWNING and RICH. They examined some 30 men who were released at the recapture of Rangoon, and who had been prisoners for 2 to 3 years. Ten subjects were found to have bilateral scotomata, with a 'tail' to the white scotoma leading from the fixation spot towards an enlarged blind spot. There did not appear to be any nuclei lying between the blind and fixation spots. There was no constancy in the colour scotomata. In not one of these 10 subjects was there contraction of the peripheral visual field either to white or to colours. All 10 showed some degree of visual failure and in five the corrected vision could not be brought above 6/60. The ophthalmological examination revealed that all 20 optic disks showed some degree of pallor. Four of the disks showed an apparent primary optic atrophy—four showed pallor of the papillomacular bundle, and eight showed pallor of the temporal half. No case showed ocular muscle paresis. No diminution of sensitivity of the cornea and conjunctiva was found, neither was there any evidence of xerosis nor any of the ocular signs of anisovitaminosis.

The authors consider that there is a relationship between the scotomata to white and those of the toxic amblyopias and that the deficiencies of vitamins B₁, B₂ and (very dubiously) A appear to play their part in the ocular signs of beriberi although the exact nature of the deficiency remains obscure. They conclude that as the optic nerve is part and parcel of the c.n.s. the damage done to the nerve proper by the axial optic neuritis of beriberi is final, and that any improvement of vision can be but slight.

ii. The ocular manifestations of malnutrition in some 500 released Allied prisoners-of-war and internees from Thailand who considered that their sight had deteriorated during captivity are discussed by RIDLEY. Among these no fewer than 100 cases of amblyopia were seen in 17 days and many of those whose corrected vision was normal had subclinical vascular lesions of the eyes. Visual failure occurred in 90 of these patients between October 1942 and December 1943 so that their sight had been defective for 2½ to 3 years. Acuity with correction varied between 1/60 and a partial 6/6 nine read less than 6/60 with the better eye sixteen 6/60 twenty six, 6/36 fifteen 6/24 fifteen 6/18 seven 6/12 eight 6/9 and four 6/6. All those with scotomata and good acuity reported recovery from temporary severe amblyopia. In many cases the onset had been sudden maximum disability being reached within a single day though in others it was gradual taking months to develop. There was some degree of photophobia and sight was particularly defective in bright light but few of the subjects complained of difficulty in seeing at night. Many patients with amblyopia gave histories indicating that in addition to recurrent attacks of the common tropical infections they had suffered from pellagra, oedema of the lower extremities dry beriberi, and from sore tongue and *perlèche* which usually accompany deficiency in the B group of vitamins. A high proportion of the cases had become nerve deaf. In the fundus there may be no visible abnormalities even when the amblyopia is severe and of long standing though in many of the severe cases there is definite pathological pallor of the temporal half of the optic disk the colour becoming grey rather than pure white. There were 48 cases of optic atrophy and 30 more were regarded as doubtful in this respect. Nothing was ever found that was suggestive of past oedema of the nerve head the retinal vessels were not constricted and the macular area and its surrounding vessels generally appeared normal though in a few instances in which temporal pallor was marked there appeared to be some reduction in the calibre of the macular arterioles a change probably secondary to retinal atrophy.

Campimetry revealed in 90 cases a small sharply-demarcated central scotoma rarely extending more than 3° and sometimes only 1° from fixation and often less though within this area in severe cases even a 40-mm white object was invisible at 1 metre. The edges of this scotoma are abrupt its density rather than its size being the important variable. In the remaining 10 cases the core of the scotoma was para- or peri-central and situated within the 3° circle the fixation area showing less visual depression. In this type the affected area was usually more extensive and the peripheral margin especially was less abrupt and extended as far as the 5° circle. In four of these cases the scotoma appeared to be limited by the horizontal meridian on both sides of the fixation point. Some patients with this type of field say that some portion of a letter or some letters in a line are invisible and that objects tend to appear and disappear. In the majority of these cases there was a history of considerable improvement during captivity which is in accordance with the shelving edge of the scotoma.

No defects were discovered in the peripheral fields.

Practically all the released prisoners showed some degree of keratoconjunctival abnormality. There was no gross injection, except occasionally in the interpalpebral area where the conjunctiva might be dull thickened or opaque. No

xerosis nor Bitot's spots were seen. In 86 per cent. of the amblyopic and 91 per cent. of the other patients the fine capillary plexus at the limbus was increased in extent and minute superficial vessels extended as far as 2 mm. into the cornea. The vascularization was accompanied by superficial opacification. Frequently the internal margins of capillary loops united to form quite large circumferential vessels. The most striking feature of the limbal capillaries was their variability in size which was often so great that aneurysms both fusiform and saccular appeared. These were situated rather more frequently on the scleral than on the corneal portion. Aneurysms were present in 65 per cent. of the scotomatous patients and in 48 per cent. of those with normal sight. No haemorrhages were observed. There seems little doubt that the lesions described are due primarily to malnutrition though there may be other factors since only a small proportion of men living under identical conditions were affected. There is no doubt that the diet was deficient generally especially in protein and fats as well as vitamins and, in the absence of direct evidence that avitaminosis unsupported by other factors is the cause it seems advisable to attribute the lesions to general malnutrition rather than simple deficiency of the B group. The abnormal vascularity of the limbus suggests a deficiency of vitamin B₂, although healthy soldiers who have been in a tropical climate for some time have some increase in the limbal plexus.

It is uncertain whether the disturbance in the visual pathway originates in the retina or the optic nerve nor is the mechanism whereby the neurones are affected understood. In view of the known abnormality of the conjunctival capillaries it is tempting to postulate a vascular origin—failure of the chorio-capillaris to nourish the outer layers at the macula or if the limitation of some fields by the horizontal meridian has any significance failure of the macular branches of the superior or inferior divisions of the central artery to nourish the inner layers of the retina. There is however no concrete evidence to support such a theory.

iii GARLAND in discussing the ocular signs in the prisoner-of-war from the Far East considers these to be a constant feature in an interesting syndrome there is also commonly bilateral nerve deafness of a varying degree with a spinal cord syndrome. The latter is usually a picture of posterior column dysfunction (but occasionally with pyramidal signs) the legs being affected more than the arms. In some cases the syndrome has been further complicated by intellectual deterioration. That this syndrome is due to a dietary deficiency seems almost certain but it seems equally certain that it has nothing whatever to do with vitamin B₁. It is very doubtful whether it has anything to do with vitamin B₂, and certainly in some of the cases the syndrome has existed throughout its course with no evidence of beriberi or pellagra. At the same time scrutiny of the diet on which the picture develops suggests that the deficiency is probably in the B group of vitamins though a deficiency of vitamin A has not yet been excluded. Garland has little doubt that some of these subjects did in fact suffer from beriberi but he suggests that the beriberi was a co-existing deficiency picture he considers that the lesion underlying the visual failure lies in the optic nerve but he does not describe it by the term retrobulbar neuritis as there is no proof that it is an inflammatory condition.

iv Ophthalmic abnormalities occurring among nearly 800 cases of deficiency disease in prisoners-of-war in Singapore and Thailand during 1942 to 1945 are discussed by CHURCHILL. Avitaminosis amblyopia (neurorretinitis) was a common condition, the first cases appearing within four months of the prisoners going on to the Japanese ration scale. In August, 1945 in one camp in Thailand, 81 men out of 1,200 were affected but a considerable number of men suffering from this condition had already died from other diseases. Of these 81 cases, 10 followed shortly on an attack of dysentery in 16 there was an association with

beriberi in 4 with stomatitis in 3 with happy feet (nicotinic acid deficiency) and in 2 with pellagra. The outstanding symptom was a blurring vision but this was preceded by a smarting of the eyes lachrymation and photophobia. When working in the sunlight many of the patients experienced actual pain behind the eyes. The blurring was first noticed on reading but soon some of the men were unable to recognize people or objects out-of-doors. The failure of sight was often progressive and severe in other cases it progressed to a certain extent and then remained stationary in others again it improved when there was any substantial improvement in the diet. These men had subjective scotomata but rough tests revealed no impairment of the visual fields. Ophthalmological examination showed a retina which was often redder than normal with swollen veins. The disk was pink and its margins were frequently blurred occasionally the temporal half of the disk was quite white. Among 72 cases some degree of cupping or excavation of the disk was present in 36 and the lamina cribrosa was seen in 8. A puzzling feature of this disease was the apparent lack of correlation between the visual defect and the extent of the ophthalmoscopic changes.

Night blindness was a rare condition among the prisoners-of-war occurring in only 3 out of 1,200 men. It was associated with only 1 of the 81 cases of avitaminosis amblyopia. This comparative rarity was probably due to the fact that pumpkins rich in carotene were a fairly constant item in the ration scale. Four out of some 1,200 men suffered from corneal ulceration and this was not more common among the prisoners than amongst British troops in the tropics.

HEAT STROKE AND ALLIED CONDITIONS

1. SPECTOR H MITCHELL H. H & HAMILTON T S The Effect of Environmental Temperature and Potassium Iodide Supplementation on the Excretion of Iodine by Normal Human Subjects *J Biol Chem* 1945 Nov v 161 No 1 137-43
11. — HAMILTON T S & MITCHELL, H. H The Effect of Pantothenic Acid Dosage and Environmental Temperature and Humidity upon the Dermal and Renal Excretion of Pantothenic Acid. *Ibid* 145-52. [15 refs.]
111. SHIELDS J B JOHNSON B C. HAMILTON T S & MITCHELL H H. The Excretion of Ascorbic Acid and Dehydroascorbic Acid in Sweat and Urine under different Environmental Conditions. *Ibid* 351-8.
- 1V JOHNSON B C MITCHELL, H H & HAMILTON T S The Occurrence of Inositol and of *p*-Aminobenzoic Acid in Sweat. *Ibid* 357-60

These papers are based on results obtained during a 2-year study of the effects of high environmental temperature and variable humidity upon the dermal losses of certain minerals and vitamins and their metabolites. Five men aged from 20 to 23 years spent eight hours a day in an air-conditioned room five days a week. The conditions were alternate weeks comfortable (86°F 50 per cent. relative humidity) and hot moist (100°F 69 per cent. relative humidity). Other conditions were sometimes imposed. The subjects were apparently at rest. Sweat losses calculated in the usual way were for comfortable conditions 80 gm per hour and for hot moist conditions 670 gm per hour (averages from pooled results of the four papers). There is one inconsistency in that in the second paper subject C is shown as sweating

[June, 1946]

at 79 gm. per hour in week 28 and in the fourth paper at 27 gm. per hour this is not a misprint, as the averages for the group are correspondingly different). The loss during comfortable conditions though high, was attributed by the author to insensible perspiration (true insensible perspiration rarely exceeds 40 gm. per hour). The mean sweat loss in hot-moist conditions varied between 40 gm. per hour and 814 gm. per hour for different weeks. There was no regular variation attributable to acclimatization. Sweat (i.e. pooled skin excretions) was collected on waterproof sheets and on swabs and was added to distilled water washings from the body clothes and utensils to form for each subject each day a single bulk specimen for analysis containing all the skin excretions for that day. On Saturday mornings undiluted sweat was collected under hot moist conditions by collecting the drips off the subjects as they stood in pans (no allowance was made for evaporation though some probably occurred). Faeces and urine were also collected and analysed.

i. *Iodine excretion*—The loss of iodine in the insensible perspiration was 2.5γ per 100 cc. when no iodine supplement was being taken, but in frank sweat (undiluted samples) it was only 0.85γ per 100 cc. The total skin loss was however greater when sweating 6.1γ per hour compared with 2.2γ per hour. A supplement of 2 mgm. potassium iodide per day did not affect the iodine losses in the insensible perspiration but increased the losses in sweat from 0.85 to 3.85γ per 100 cc. (undiluted sweat) and from 1.5 to 17.7γ per hour. The urinary loss was in all cases more than 75 per cent. of the total excretion but it was slightly less in hot moist conditions, than in comfortable conditions when an iodine supplement was given, thus balancing the increased skin loss. Faecal excretion after extra iodine was greater in hot moist than in comfortable conditions but it was the same under both conditions without the supplement.

ii. *Pantothenic acid excretion*—About 8γ of pantothenic acid were lost per 100 gm. insensible perspiration. Undiluted sweat contained 3.8γ per 100 cc. increasing the relative humidity did not significantly increase the concentration. Losses of pantothenic acid per hour from the skin were about 8γ under comfortable and 25γ under hot moist conditions. Supplements of up to 18 mgm. calcium pantothenate per day did not increase the concentration in either insensible or sensible perspiration. Urinary excretion of pantothenic acid was slightly greater under hot moist conditions but the proportion of the total excretion found in the urine fell from 97.6 per cent. to 87.3 per cent. owing to the very much greater rate of excretion via the skin. Thirty-one per cent. of an 18 mgm. dose of calcium pantothenate was recovered from the urine. The authors discuss their results in relation to the fact that they used results by other workers and attribute differences to the fact that they used *Lactobacillus arabinosus* as test organism whereas others had used *Lactobacillus casei* which may be stimulated by fatty materials in the sweat.

iii. *Ascorbic acid excretion*—No rubber equipment was used in the study as it has repeatedly been shown that sweat which has been in contact with rubber reduces 2, 6-dichlorophenol-indophenol and hence has an apparent ascorbic acid content whereas sweat collected in other ways has no such reaction. By the indophenol method only 9 out of 82 samples of sweat were found to contain ascorbic acid but by the 2, 6-dinitrophenyl-hydrazine procedure of Roe and another free ascorbic acid was found in five out of eight specimens tested, in a mean concentration of 33γ per 100 cc. By the same method an average of 70γ of dehydroascorbic acid was found per 100 cc. of sweat. In one experiment daily doses of 500 mgm. of ascorbic acid decreased the ascorbic acid content of the sweat from 33γ per 100 cc. in the control week to 5γ while the dehydroascorbic acid content increased from 34γ to 107γ per 100 cc. In another period and with the same daily doses the dehydroascorbic acid content was only 68.5γ per 100 cc. The combined skin losses of ascorbic

and dehydroascorbic acids were equivalent to 2.74 mgm only per day even with profuse sweating hence skin losses do not noticeably affect vitamin C requirements. Urinary losses of ascorbic acid were greater at high humidities than under comfortable or hot-dry conditions.

Inositol and p-aminobenzoic acid excretion—The concentration of inositol in sweat was found to be 21% per 100 cc. under hot moist conditions the loss per hour was 0.118 mgm. compared with a loss of 0.027 mgm under comfortable conditions. Urinary excretion was variable. The average concentration of p-aminobenzoic acid in sweat was 0.24% per 100 cc.

BURCH G E The Influence of Environmental Temperature and Relative Humidity on the Rate of Water Loss through the Skin in Congestive Heart Failure in a Subtropical Climate. *Amer J Med Sci* 1946 Feb v 211 No 2 181-8 4 figs [11 refs]

Water losses were measured from three small areas of skin first in a comfortable atmosphere (dry bulb 70°F wet bulb 62°F relative humidity 60 per cent) and then in a hot humid atmosphere (dry bulb 104°F wet bulb 83°F relative humidity 64 per cent). The areas chosen were the tip of the index finger on the shin and on the volar surface of the forearm all on the right side. The measurements were made by directing a stream of dry oxygen over the skin and then condensing the water taken up the amount recovered being estimated gravimetrically. Five groups of subjects were tested (a) eleven normal subjects (b) ten patients with diseases other than congestive heart failure (c) five patients with slight to moderate failure (d) five patients with moderate to severe failure (e) ten patients with severe failure. Under comfortable conditions the losses were the same in all groups with finger losses about 50 per cent greater than skin and forearm losses. In hot humid conditions finger losses showed a 4-fold increase and the other losses more than an 8-fold increase (compared with the losses under comfortable conditions) in the normal, non heart failure and slight heart failure groups but in the moderate and severe heart failure groups finger losses increased only 2.5 times for both groups and the other losses 4 times and 2.5 times respectively. Thus local sweating in these two groups was impaired relative to the rest.

Thus impairment of local sweating is Burch considers a manifestation of congestive heart failure [he is no doubt correct but he weakens his case by drawing his main conclusions from the comparison between a control group average age 26 comprising nine white men one white woman and one coloured woman and a severe heart failure group average age 54 comprising four coloured women three coloured men and one white man]. Diminished local sweating indicates Burch argues a generalized and marked impairment of the emergency sweating mechanism predisposing to the accumulation of body heat. [He would be on surer ground if he had taken measurements from more areas see WEINER, this *Bulletin* 1946 v 43 249 no measurements are given of the body temperatures in any of the subjects though reference is made to observations by other authors on pyrexia in patients with congestive heart failure in comfortable environments.] The ability to sweat Burch states returns with recovery of the cardiac function but no serial observations on a patient during recovery are given in support of this. In his discussion the author emphasizes the importance of cool comfortable conditions for patients with congestive heart failure in order to keep the demand on the cardiovascular system as low as possible and he therefore recommends air-conditioned wards especially in warmer climates.

Koch W. Three Rapid Tests for the Estimation of Thermal Fitness of Fabrics. *J Hygiene* 1946 Jan. v 44 No. 4 288-8, 3 figs.

The author suggests that the fabric for use in the tropics may be decided by considerations of its thermal insulation quality and its air porosity only. After describing how an estimate of insulating power can be obtained by comparing the cooling rate of a keta thermometer clothed with the fabric with the cooling rate when it is uncovered, this author discards this in favour of a simple measurement of thickness. REES (*J Textile Inst* 1941 v 32 T 149) showed that thermal insulation, measured in the laboratory is among other things a function of the thickness of the fabric. Koch accepts this as applicable to physiological conditions, and describes a simple optical method of measuring thickness. Instead of measuring air porosity, he suggests that the head of pressure necessary to force mercury through an unsupported stretched layer of the fabric should be determined. He found a correlation of -0.78 between the two values when plotted fall accurately on a rectangular gives relating the two values and the air permeability the figures he hyperbola and are probably therefore not his original experimental data. [Physical considerations would in any case suggest the hyperbolic relationship.] (The author completely ignores other physical properties of fabrics such as water vapour permeability and water absorbing power.) BRIKTON, D. An Unusual Form of Epidemic Food-Poisoning with Neurological Symptoms. *Proc Roy Soc. Med* 1948 Feb v 30 No 4 173-5 (Sect. of Neurology 5-7)

During 13 months October 1942—November 1943 some 450 persons in Aden had suffered from *misra* poisoning from eating imported wheat contaminated by the weed flax-darnel or *Lolium temulentum*. The local word *misra* is said by the author to mean tropy and the symptoms are very characteristic of this state: dizziness, headache, tremors, lassitude, slurred speech and staggering gait, sometimes gastro-intestinal disturbance. If much has been taken the patient may become comatose for several hours. No deaths were reported. The condition recorded and the fact that in ordinary circumstances Abyssinian wheat are rare is due to the care with which the weed is separated from the wheat.

The actual toxic element is said to be some pyridine base in the mould seen on nearly every weed-seed. [This form of poisoning has been known in India for many years. Concerning it the reviewer wrote in 1920 " *Lolium temulentum* bearded darnel, known as mostaki (Punjab) and moschni (N. W. Provinces). Bread made with flour partly constituted by the seeds of this plant sets up the following symptoms: vertigo, staggering gait, nausea, vomiting, dim vision (perhaps green), tremors of arms, legs and tongue with dysarthria, a burning pain in the mouth and throat, and general prostration with a weak, irregular

pulse. No fatal cases have been reported. It is not known whether the poisoning may not be due to an associated symbiotic fungus. *The Practice of Medicine in the Tropics* Byam & Archibald 1921 v 1 782.] H Harold Scott

COHEN S C EMERT J T & Goss C C Poisoning by Barracuda like Fish in the Marianas. *U S Nav Med Bull* 1946 Feb v 46 No 2 311-17 2 figs

Two outbreaks of food poisoning are recorded in the same district one affecting 41 persons of an officers mess in a Military Government camp on Saipan the other affecting 10 civilians (Koreans) in an internee camp on Saipan. The poisoning is ascribed to eating barracuda like fish from which it would be inferred that the actual diagnosis was not made but the article is illustrated by drawings of *Sphyræna barracuda* and *Ruvettius pretiosus* (oil fish).

The fish eaten in the officers mess was a large one 55 lb and was eaten 27 hours after being caught at the internee camp the 10 poisoned were among 30 who partook of it 8 hours after it had been caught. Both fish had been caught at the same time and at the same place.

The symptoms were typical. About 4 hours after eating the fish there set in severe muscular spasms of the limbs with cold clammy extremities paresis of the muscles of deglutition dyspnoea aphonia burning sensations in the mouth and tongue and cutaneous hyperaesthesia so that cold drinks and cold baths could not be taken. There was in most a certain degree of shock. Just a year previously in the same Journal Feb 1945 a closely similar outbreak due to the same cause and in the same area was reported [see this *Bulletin* 1945 v 42 592 where a fairly full comment is given] H Harold Scott

MENON I G K. Intestinal Fusio-Spirochaetosis. *Indian Med Gaz* 1945 Sept v 80 No 9 454-8 7 figs on 1 pl.

The author found fusiform bacilli (*Fusiformis fusiformis*) and spirochaetes (*Treponema vincenti*) in the faeces of 16 out of 120 persons examined. Notes of clinical and laboratory findings and of treatment are given in the case of four of them and the other twelve are tabulated under the headings clinical condition cellular exudate other infections and spirochaetes. In the four cases described there were sudden attacks of abdominal pain above the umbilicus and of diarrhoea lasting for a day or two or sometimes for a few weeks. Duodenal intubation was done in one patient and spirochaetes and fusiform bacilli were found in the fluid withdrawn. These organisms were present on the gums of all four patients. Of the other 12 patients 4 had amoebic dysentery and 2 had a history of amoebic infection 2 had pain and diarrhoea one had chronic dyspepsia 1 had upper abdominal pain and 2 had no symptoms. *Giardia intestinalis* was present in 6. Treatment with stovarsol appeared to cure the symptoms. The possibility that the fusiform bacilli and spirochaetes may cause the symptoms with which they are associated is discussed with references to the work of other authors. J F Corson

BOLAND E W HEADLEY N E. & HENCH P S The Treatment of Agranulo-
cytosis with Penicillin. *J Amer Med Ass* 1946 Mar 2, v 130 No 9
556-9, 1 fig [Refs. in footnotes.]

Since 1941 sulfonamides and penicillin have been used in the treatment of granulocytopenia or agranulocytosis. At first they were used more often despite the presence of agranulocytosis rather than specifically for it. Seven cases of agranulocytosis successfully treated with sulfonamides have been reported. But because sulfonamides may themselves produce agranulocytosis penicillin would seem to be the remedy of choice.

Ten cases of agranulocytosis including the one here reported have now been treated with penicillin prompt recovery has occurred in every case. This represents a notable improvement in the treatment of the condition and allows for much greater optimism in prognosis than has heretofore been possible. In some of these 10 cases leukopoietic agents were used in conjunction with penicillin but the current trend is to rely on penicillin alone. Experiences to date indicate that penicillin constitutes the most potent remedy at hand for the prevention or control of the serious potentially fatal complication of agranulocytosis.

Since this paper was submitted for publication another case of agranulocytosis successfully treated by penicillin has been reported. Thiouracil had been given for hyperthyroidism the leukocyte count fell to 2 400 with 2 band cells and 2 segmented neutrophils. Treatment included a transfusion liver extract and a total dose of 560 000 units of penicillin in four days after which recovery was complete.

KEAN B H TUCKER, H. A & MILLER W C Ainhum a Clinical Summary
of Forty-Five Cases on the Isthmus of Panama *Trans Roy Soc Trop*
Med & Hyg 1946 Feb v 39 No 4 331-4

In the 40 years ending May 1944 45 cases of ainhum have been traced in Panama this number represents 1.5 per 10 000 West Indian male admissions to hospital. All the ainhum patients were West Indians 20 from Jamaica 10 from Barbados they were all males and none was white or half-caste. Thirteen were between 21 and 30 years of age at the onset of the disease 11 between 41 and 50 8 between 31 and 40 Six had the condition before coming to Panama and in two-thirds of the cases just over 11 years elapsed between arrival in the district and onset of symptoms. The little toes were involved in all both sides in 14 the right alone in 18 the left alone in thirteen. In one patient the third and fourth toes were affected, also on both sides. In one only was there a family history the father having been similarly afflicted.

Pain was marked, in fact the chief symptom for which hospital relief was sought. A history of local trauma was elicited in 4 only. No evidence was obtained of any aetiological connexion between ainhum and leprosy, syphilis, scleroderma or arteriosclerosis and the author postulates hereditary racial tendency as the main factor (which if it has any meaning at all is purely hypothetical.)

H Harold Scott

"To a total of 1,200 cases in the literature 12 cases are added. All the patients were American Negroes. The incidence is seen to be higher in Negroes than in the general population. The data on these additional cases include age and sex of patient type of tumour nodularity presence or absence of cirrhosis necrosis hemorrhage and extrahepatic metastases weight of the liver when available.

In the genesis of the disease the role played by cirrhosis is important.

Experimental carcinogenesis suggests dietary deficiencies acting as predisposing factors in explanation of the peculiar racial and geographic distribution of the disease.

TAYLOR C. E. The Racial Distribution of Nephritis and Hypertension in Panama. *Amer J Path.* 1945 Nov v 21 No 6 1031-4 1 fig [37 refs]

[Renal disease is one of the most obscure in human pathology and this article forms an interesting pathological study but leaves the question little if at all less obscure.]

For some years it has been known that racial groups living in Panama in close contact and under similar conditions show marked differences in the incidence of hypertension. Thus it is some seven times as common in the West Indians as in native Panamanians and in the younger age-groups the proportion might be as high as 16 to 1 as gauged by examination of more than 1,300 persons applying for employment. African negroes under natural i.e. primitive conditions generally have a relatively low blood-pressure and it is suggested that an important factor in causing the hypertension is adjustment to a new civilization and a new environment. [This by itself, is of course pure hypothesis.] The author has studied autopsy records for renal changes among 498 cases: 268 West Indian negroes 77 Panamanians 135 whites, and 20 miscellaneous. He presents by way of preliminary a table of histological criteria, dividing the renal changes into three main groups: glomerulo-nephritis (acute subacute or chronic) pyelo-nephritis (acute active chronic and healed) and nephrosclerosis (arterial and arteriolar) a fourth group in which the other three may be combined he designates "unclassified".

Generally in the whole number of 498 pyelo-nephritis was the most common nephrosclerosis fairly common glomerulo-nephritis relatively rare. The numbers in the races examined are so unequal that comparison except on general lines is of little value and as given in percentages the findings are apt to mislead or convey a wrong impression. But broadly speaking differences were striking. Thus among the West Indians half (49.3 per cent.) had some form of nephritis more than three times relatively as frequent (15.6 per cent.) as among the Panamanians among the whites it was 20.7 per cent. Pyelo-nephritis was twice as frequent in the West Indians as in the other races the arteriolar form of nephrosclerosis was more than seven times as common in the West Indians as among the Panamanians and three times as common as in the whites. Blood pressure readings were of the same order. West Indians 176/104 whites 159/88 Panamanians 136/89. Sex seemed to play no part in the distribution of renal disease and it is noted that "five per cent. of the negroes and whites had mild hypertension with no evidence of nephritis". The author suggests as an interpretation of this that "essential hypertension may occur in the whites and the West Indians whereas when hypertension develops in a Panamanian it is probably secondary to renal mischief."

GENERAL ENTOMOLOGY

DETHIER V. G. The Transport of Insects in Aircraft. *J Economic Entom.* 1945 Oct v 38 No 5 523-31

From December 1943 to April 1945 816 collections of insects were made in aircraft flying between India and the west coast of Africa. The author groups the 2,006 insects collected into 86 families and 13 orders. The order Diptera constituted 88.5 per cent of the total catch, and one species *Unscia sorbens* accounted for 45.9 per cent. of all insects caught. Only ten mosquitoes were taken, owing to precautions observed at the airfields. There were some *Simulium griseicollis* between December and February in the Sudan, but no *Phlebotomus* during the sandfly season March to September.

The insects gain entry to the cabin when the aircraft is grounded—they either fly in or are carried in on passengers or cargo. There is no evidence that they enter during flight of the aircraft. No insects were found in the engine nacelles and the only species taken from dismantled or wrecked wing and tail spaces was *Unscia sorbens*.

One hundred tests were made with caged *Anopheles gambiae* placed in the nacelles for flights ranging from fifteen minutes to four hours duration. In 99 instances all mosquitoes were dead after the flight and in one test they were so battered that they died soon after removal. Other tests showed that insects in the nacelles were killed during the take-off.

The author concludes that effective precautions taken on air fields reduced the number of insects entering the aircraft and that along the route studied insect control in the aircraft themselves is necessary in the cabins only.

BEAMENT J. W. L. Waterproofing Mechanism of an Insect Egg. [Correspondence.] *Nature*. 1946 Mar 23, 370

WEBB J. E. The Penetration of Derris through the Spiracles and Cuticle of *Melophagus ovinus* L. *Bull Entom Res* 1945 July v 36 Pt. 1 15-22 1 fig. 16 refs.

In *Melophagus ovinus* derris dust is shown to be absorbed through the spiracles and tracheal system. The amount of dust entering the tracheae is governed by the structure of the inspiratory spiracles and the rate of flow of the inspired air.

"Factors stimulating the rate of respiration of the insect—i.e. increased muscular activity, the presence of 5 per cent. carbon dioxide and a rise in temperature increase the rate of entry of derris into the body.

"Penetration of derris takes place slowly through the external cuticle at 30°C., but not at all at 20°C. It is postulated that the entry of derris through the cuticle probably depends on the hardness of the lipoid layer.

WEBB, J. E. & GREEN R. A. On the Penetration of Insecticides through the Insect Cuticle. *J Exper Biol* 1945 Dec v 22, Nos. 1/2, 8-20 2 figs.

Some previous observations showed that certain insecticides, e.g. Derris were more effective in the presence of solvents such as high boiling tar acids.

Since it seemed likely that the solvents acted by facilitating penetration an investigation into this possibility was undertaken.

Diphenylamine was chosen as the insecticide since it is soluble in a wide variety of organic solvents. It was first mixed with kaolin and 1 per cent by weight of the solvent was then added.

The sheep ked *Melophagus ovinus* was used as the test insect. Groups of five keds in corked specimen tubes received liberal doses of insecticide and were later examined for cessation of heart beat. In a previous paper by Webb [above] it was shown that dermis dust entered the spiracles in the present instance however such entry is negligible and the diphenylamine acts after absorption through the cuticle.

It was found that only certain solvents of diphenylamine increased the rate of action e.g. cresols, benzyl alcohol and 4-methyl-cyclohexanol. Other solvents for example carbitol and methyl benzoate did not produce this effect. The capacity of a solvent to induce rapid action is described as its carrier efficiency.

It is suggested that the cuticle covering an insect may be thought of simply as a two phase system comprising an outer phase of lipophilic elements associated with the epicuticle and an inner phase of hydrophilic elements associated with the exocuticle and endocuticle which is traversed by lipophilic elements. If this concept of the cuticle structure is accepted it can be seen that in order to reach the hypodermal cells below the cuticle the penetrating substance must traverse first a lipophilic and then a hydrophilic layer. Measurements were made of the rate of passage of solvents through beeswax (taken to represent the lipophilic layer) the solubility of the solvents in water, the partition coefficients of the solvents between beeswax and water, the solubility of the diphenylamine in aqueous solutions of the solvents and the volatility of the solvents. It was concluded that a high carrier efficiency could be correlated with a high rate of penetration through beeswax, a high partition coefficient of the solvent between beeswax and water and a high solubility of insecticide in a solution of the solvent in water. The volatility of the solvent and the solubility of the insecticide in it were also relevant factors.

As a result of the above observations it is suggested that solvents which facilitate penetration do so by transporting the insecticide across the lipid elements of the epicuticle to the interface between this layer and the water of the exocuticle. They also concentrate the insecticide in the epicuticle/exocuticle interface and so by raising the concentration there increase the diffusion gradient. Finally the solvents diffuse into the exo- and endocuticle and raise the partition coefficient between the solvent in the epicuticle and the water in the exocuticle.

Mixtures of two solvents each deficient in some of the above properties but together possessing all the essential physical properties showed a carrier efficiency higher than that of either constituent alone.

Besides diphenylamine the results were shown to apply to dioxanthogen ω -nitrostyrene dibromide and rotenone but it does not necessarily follow that the carrier efficiency of a solvent is the same for all insecticides.

LATYSHEV N. I. [Instructions for testing of Sandfly Repellents.] Med. Parasit. & Parasitic Dis. Moscow 1945 v 14 No 2, 82-5 [In Russian.]

The author points out that very little is known regarding chemical methods of protection against sandflies and discusses the methods of testing repellents and the results of some tests with sandflies. Observations on the efficacy of the repellents can be carried out by applying the chemical (1) to one side of the face or to one arm while leaving the opposite side of the face or the other arm untreated (2) to one individual and using a second one as control (3) to one part of a window leaving the other free (4) to whole groups of people with adequate controls. In the case of (1-3) the repellent effect is determined by comparative counts of sandflies while in (4) it is assessed on the basis of evidence of bites.

The following repellents have already been successfully used against sandflies (1) bis-ethylxanthogen (Preparation A. see also this Bulletin 1945 v 42, 940) used as a 3-5 per cent. solution in vaseline (2) 3 drops each of anise oil eucalyptus oil and turpentine, lanolin 30 gm. (3) turpentine 10 parts tar 4 Dalmatian powder and castor oil 20 of each lanolin and vaseline 40 of each (4) Japanese menthol 1 part, dilute carbolic acid 2 vaseline 100

Good results against other blood-sucking Diptera were obtained with wide-meshed nets impregnated with one of the following repellents and worn on the head (1) lysol 90 parts, turpentine 10 vegetable oil 5 water 55 (2) 5 per cent. solution of caustic potash to which 10 per cent. of tar is added. It is suggested that the effect of these repellents on sandflies should also be tested.

ARTHUR, W. P. Habituation of *Pulex irritans* to Animal Host. [Correspondence.] Trans. Roy. Soc. Trop. Med. & Hyg. 1946 Feb. v 39 No 4 343-4

The author relates a personal observation which showed that *Pulex irritans* may become adapted to live on a dog. His spaniel was accidentally found to be infested with this species of flea, 100 being recovered from it. He had the dog on his knees and carried it in his arms but no fleas passed from the dog to infest him though he is ordinarily attractive to fleas. The fleas were removed from the dog in an unoccupied room and some escaped when the author entered the purposely lighted room and four days afterwards the fleas bit him. A few fleas taken to him on the dog for over a year in spite of all the house of them. None of the other five occasions.

LABORATORY PROCEDURES

LILLIE R. D. *Effect of Metals on Giemsa Stain Solutions in Fifty per cent Glycerol and Methanol Mixture.* *J Lab & Clin Med* 1946 Feb v 31 No 2 253-6

During the recent world war a batch of Giemsa stain solution deteriorated after the bottles had been issued to various places the eosin staining being lost. The bottles had screw caps lined with tin foil seals and these were noticed to have a yellow incrustation. The tin foil was later found to consist of tin (99.7 per cent.) with small amounts of lead, copper, arsenic, antimony and iron. Experiments were made with the tin foil and with various metals to see what effect they had on Giemsa stain solution as indicated by spectroscopic examination. The results are given in tables: it was found that various metals relatively active in the electrolytic series decompose thiazine eosinates in glycerol-methanol solution [Giemsa's stain] and remove eosin from the solutions. Alkali earth metals appear to act purely as alkalis. Zinc acts on methylthionins but not on thionin.

The authors conclude that tin foil or other foils containing tin, zinc or cadmium should not be used for lining screw caps for Giemsa's stain; paraffined cardboard is satisfactory for the purpose.

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

MEGAW J. *The Health of India.* *Brit Med J* 1946 Mar 9 343-7

This appraisal of the health of India by a recognized authority is concerned almost exclusively with the practically universal malnutrition caused by insufficient and unsuitable food. In countries in which malnutrition and infectious diseases have been reasonably well controlled, the average length of life has increased to well over 55 years. In India, where much has been done to control infectious disease but little or nothing to tackle the malnutrition problem, the average length of life is but half this figure. The control of epidemics has contributed to a prodigious increase in the rate of growth of the population. Between 1931 and 1941 the increase of population for the whole of India was 15 per cent, an actual increase of about 50,000,000. In parts of India the increase attained 22 per cent. The people must choose for themselves whether to adhere to the present system of unrestricted propagation of children with its attendant misery or voluntarily to apply an adequate check. The magnitude of the problem as set forth is staggering and this lecture was delivered before the imminence of widespread famine that faces India today was recognized. Increase in the production of food can scarcely keep pace with population increase unless drastic changes are made in outlook of life and manner of living. The abolition of uneconomic small holdings and the elimination of millions of useless cattle would be fiercely resisted.

The creation of a Commission is urged, to make an unbiased report on social and other customs which cause ill-health and economic depression in the rural population and to recommend suitable action to effect a change. The Commission should consist of enlightened Indians especially Indian women. Such a Commission might create a sense of danger needed to convince the people of the need for a change in their plan of life.

WOOLLEY E. J. S. The Health of the Civilian Population of Tristan da Cunha. *J Roy Soc Med Ser* 1946 Jan. v 32, No 1 3-15 7 figs

Tristan da Cunha is no longer the *terra incognita* it was at the beginning of the century but this account is interesting in bringing information concerning the island up to date. The settlement has been in existence for 130 years and the population in 1944 was 122. Registers of marriages and births have been kept since 1871 and 1880 respectively and of deaths since 1892. The types of inhabitants range from whites with fair hair and blue eyes, to dark mulatto. The adults are of good physique the children and adolescents are not this is ascribed to deterioration in the standards of living for since there is less trade with passing ships the people have to depend more on their own efforts and the crops consist almost entirely of potatoes this food being supplemented by pumpkins fish and a few eggs of sea birds and fowls. Of late years there has been a little grazing, and consequently a little milk production. The island has no alcoholic drink. Living conditions are still primitive—houses of stone roofed with New Zealand flax or tussock grass sanitation is hardly existent. If buckets are used they are neglected as soon as they are full or are emptied in heaps near the dwellings.

Epidemics of colds and tonsillitis occur but there are no authentic records of any other epidemics if we except outbreaks of mild enteritis in the summer months when flies are a pest. Many suffer from local sores whitlows boils cellulitis impetigo which heal with difficulty and slowly. *Ascaris lumbricoides* is found to infect almost the entire population. The commonest disease is asthma (97 cases) next is fibronitis (18) and dyspepsia (11). In spite of the severity of the common cold, pulmonary disease is rare. Labour is usually easy and maternal mortality is nil children are breast-fed for a year or so but after 4 months they are given in addition potato and the infants are undernourished anaemic and dyspeptic. Hereditary deformities are noted nine descendants of one woman show deformity of the pinna, with partial or complete mental occlusion others showed polydactyly and "lobster hand". Intelligence is not easy to gauge because of the isolation of these people but 152 are said to be "normal" able to support themselves and their families and to be educationally receptive 43 are dullards feckless improvident, lazy and lacking in initiative but capable of working under supervision nine are "high grade defectives." [This account of the general state and mode of life of these islanders makes gloomy reading—a marked contrast with the happy healthy lives of the early inhabitants of the former lonely Pacific island Pitcairn.]

H Harold Scott.

BLANCHARD M. Quelques particularités de la pathologie de Madagascar [Remarks on Disease in Madagascar] *Les Grandes Endémies Tropicales*. (Onzième Année) 1939 Paris. pp. 5-13.

This is of the nature of a farewell talk by Inspector-General Blanchard. In it he refers in a few words to each of the following subjects. Plague yellow fever trypanosomiasis smallpox, and typhus in a group of infectious diseases. The chief point to note in this group is the possibility of introduction of yellow

fever. The author does not think that infective *Aedes* are likely to be brought in and the chief danger is from persons in the incubation or early stage of the disease. A second group he mentions is that of endemic diseases and here he refers briefly to malaria syphilis tuberculosis leprosy beriberi and rabies. The proposal has been made to decentralize large leprosaria and collect or re-group the inmates in small villages of 6 to 30 patients near medical centres and near their own homes. Other conditions briefly referred to in this paper are uratic deposits alcoholism intoxication by *Cannabis indica* the last of which is becoming more common as the price of tobacco rises. The only surgical condition spoken of is bites by caymans and in this connexion he cites a case which occurred in 1938. [The article is interestingly written but consists in the main of general remarks nothing new being contributed there are many things one would expect to find mentioned but they are not even referred to such as the use of the living E V strain of *P. pestis* in prophylaxis in Madagascar]

DAVID J. Une oeuvre française aux îles Wallis et Futuna [French Work in the Islands of Wallis and Futuna.] *Les Grandes Endémies Tropicales* (Onzième Année) 1939 Paris. pp 72-82. H Harold Scott

VAUCEL. L'aspect social de la médecine aux Colonies. [The Social Aspect of Medicine in the French Colonies.] *Arch Méd Sociale* Paris 1945 Aug v 1 No 5 325-8

The author makes the point that in the colonies medicine is social in so far as it copes with diseases which are widespread and that for this purpose campaigns on a large scale are deliberately planned. [This recalls the remark made in Lord HAILEY's *African Survey* that disease of the type which causes most mischief in Africa is generally a mass infection and must be attacked in the mass. See this *Bulletin* 1938 v 35 934] Instances of this kind of campaign are given. The sleeping sickness treatment services in West Africa examine 6 000 000 persons each year among whom about 20 000 cases of sleeping sickness are discovered annually. The epidemic has been stabilized and the infection rate is now about 0.5 per cent. For the prevention of yellow fever more than 10 million people have been vaccinated by the scarification method. In Madagascar extensive use has been made of the live E V vaccine in 10 years five million people have been vaccinated and the incidence of plague has fallen from 3,584 cases in 1934 to 184 in 1944. The author writes in general terms on the provision of a service of travelling units for the discovery treatment and prevention of the major diseases which should achieve a standard of efficiency much greater than is possible under the present system of fixed dispensaries.

DE BRIEY P. Migration of Indigenous Workers in the Belgian Congo. *Internat Labour Rev* 1945 Oct v 52 No 4 335-51 [Refs in footnotes] Charles H Ilcocks

In an earlier paper Dr Margaret READ discussed the effect of the migration of African males from Nyasaland in search of work upon the communities left behind [this *Bulletin* 1942 v 39 723]. In the present paper de Briey discusses the same problem and the regulations formulated to deal with it in the Belgian Congo. The least harmful form of migration is the seasonal search for work when the men take employment for a short time only away from their homes. In this form there is relatively little interference with village economy and the men retain a strong connexion with their own communities. Much more serious in its effect on the men and on their families is the migration for work which entails absence from home lasting for 3 years or so especially...

the place of work is far from the village. Under these circumstances the men are suddenly placed in unfamiliar surroundings, to which they may react badly for themselves and their people. The age and sex balances of the villages are seriously disturbed if many men are away for long periods. The situation is less harmful if the place of work is near the homes of the workers.

The treatment of men detached from their home surroundings must obviously be considered with special care more especially if they have been recruited for work under conditions of which they have no exact understanding there are, therefore, special regulations governing the recruitment of labour. In the Belgian Congo measures have been taken to protect both the indigenous community and the indigenous worker. For the community from which the workers are drawn there is a land policy by means of which the Government tries to prevent the complete exhaustion of the labour supply in some areas by directing settlers from Belgium to areas where manpower is plentiful. There is also a social policy. The governor of a province may prohibit all recruitment of Africans if recruitment would mean that an undue proportion of men (over 10 per cent. of able-bodied men, that is over 2.5 per cent. of the whole community) were removed from the district. Reduction of the male population beyond this figure entails risk to the health and even to the continued existence, of the community. In formulating this principle the Government have taken into account that spontaneous application for employment does occur among the Africans, and that the number of persons thus actively seeking work is considerable. It is impossible to prevent those Africans from going to work who of their own accord, show that they wish to contract an engagement the restrictions, therefore, apply only to active recruitment.

It is realized that if large concessions are made to Europeans in some areas the attractions offered to the Africans may be so great as to tempt away the whole male population from their homes. This would, however, not necessarily be so disastrous as recruitment because experience has shown that under some conditions the family of the African would accompany him. Nevertheless, the social consequences would be serious unless adequate steps were taken to provide for the welfare of these families in their change to a new life. "It is precisely the function of a colonial Government to create economic conditions tending to give the indigenous population a stable social environment adjusted to its degree of development." Attempts are therefore made by companies to stabilize the indigenous workers in their new surroundings by favouring long term engagements and by providing for the health and well-being of the

Periodical wage increments and bonuses for married men and those inducement to stay and to bring wives and families. Medical services are provided, in one case costing 10 per cent. of the total cost of indigenous labour employed. Education is also provided, and social institutions which cover a wide range of activities are encouraged. These efforts have been successful in creating new and stable communities. Stabilization will not abolish the evils which may attend the process of turning the tribal Africans into an industrial proletariat, but it will make them smaller.

The author concludes with the remark that whatever measures the Government adopts to deal with this complex problem success will depend on the human factor [The line of thought that runs through this paper is very similar to that propounded by Sadi (this Bulletin 1948 v 43 257). The medical reader may draw the conclusion that since the impact of industry on the African will affect both his physical and mental health, it is the duty of Governments to seek the advice of their medical officers, much more than has in the past been the case, as to the measures to be adopted, and that the purely commercial point of view should not be given the priority it has too long enjoyed.]

Charles H. Nicolson.

WRIGHT SMITH R J A Case of Fatal Stabbing by a Stingray *Med J Australia* 1945 Dec. 22 v 2 No 25 466-7 2 figs

G P WHITLEY in his work on *The Fishes of Australia* describes six varieties of stingray in Victorian waters. The spine is strong and can be driven through the side of a boat and the fish can show great accuracy in stabbing. They often come into shallow waters for warmth and lie in the sands.

The case here recorded is that of a man of 33 years a powerful swimmer who when coming in from a bathe suddenly showed symptoms of distress he was helped in by friends and was breathing with difficulty. 20 minutes later he died. There was an oval shaped stab wound $\frac{1}{2}$ -inch long at the fifth left intercostal space found at autopsy to have penetrated the pleural cavity and the pericardium and there was an irregular tear of the left ventricle $\frac{3}{8}$ th inch in length near the apex. There was a smaller wound not penetrating beyond the subcutaneous tissue on the mesial side of the first. The pericardial sac was found to contain fluid blood and there was much blood and some clot in the pleural sac and haemorrhage round the wound in the left ventricle. The organs generally were healthy. The palings of the fence round the bathing place were broken and the stingray may have thus gained entrance. The water was dirty and nothing could be seen on the sea bed no weapon spike or nail was found which might have caused the injury [but nor was any stingray]

BOOK REVIEWS

Manson's Tropical Diseases. A Manual of the Diseases of Warm Climates.—
Edited by Philip H. MANSON B.A. M.C. D.S.O. M.A., M.D. D.T.M. & H. Cantab. F.R.C.P. London Senior Physician to the Hospital for Tropical Diseases London etc. Twelfth Edition.—pp. xiv + 1068 17 colour pls. 9 half tone pls. 407 text figs. 6 maps & 29 charts. 1945 London Toronto Melbourne & Sydney Cassell & Co. Ltd. [42s.]

Manson's Tropical Diseases under the able and indefatigable editorship of Sir Philip Manson-Bahr goes from strength to strength. In the five years since the eleventh edition was issued there have been momentous happenings hundreds of medical men have been serving in the tropics for the first time and have met with diseases new to them, and differences in diseases with which they were familiar in temperate climates. These have rushed eagerly into print to record their experiences and the result has been a spate of literature some of it of value, but much of it everyday matters to readers of this *Bulletin* with their extensive tropical experience. Also the fact of having large numbers of men fresh to tropical conditions under their care has afforded a unique opportunity for the more experienced to carry out research in the field on a large scale and to apply measures already tested and found successful in the laboratory. To sift all this vast amount of material, to separate the wheat from the chaff and present the wheat in a palatable and assimilable form has been the self-imposed task of the Editor and admirably has he performed it. He acknowledges freely and fully the help he has received from the Bureau of Hygiene and Tropical Diseases and its *Bulletin* and from the annual summaries of the previous year's

progress in all the important tropical diseases, which epitomize the abstracts made in the *Tropical Diseases Bulletin* on the several subjects during that year.

There is hardly need to review in full a work of such popularity as this. Its usefulness is obvious in the fact that a new edition has been called for every 4-5 years since it first saw the light and that in addition it has been reprinted no less than 17 times. Since the last edition was published in 1940 several matters which were then *sub judice* or obscure have been decided or solved necessitating modification in presentment. Suggestions then put forward for the consideration of the Editor have been carefully weighed and a number of them adopted.

In view of the developments in tropical medicine which have taken place in these five momentous years in the history of medicine and in particular of tropical medicine the Editor has found it necessary to recast some sections and to re-write others afresh to re-draw some of the illustrations and add new ones nevertheless, so ably has this been accomplished that though there are 43 more text-figures the whole book is 15 pages shorter than the 11th edition. New matter which is exceptionally welcome includes a chapter on the Technique of Injections and Blood transfusion and a list of special drugs used in the treatment of tropical disease may more than a list for in the case of each we are given its common synonyms its chemical constitution and formula its therapeutic application and dosage. This is indeed, a boon but the section will need constant revision as new drugs are introduced some to replace old ones which will drop out, others to serve new ends.

To pass to matters of detail. There are signs on almost every page of most careful revision even to cutting out of single words to save space if the sense is not endangered thereby. Again, by printing two lines more on a page more space has been gained so that the new edition with more letterpress has even fewer pages than the last. This edition has 7 plates fewer than the preceding. we are sorry to miss the one depicting alastrum and that of the macular rash of leprosy. Whether it was wise to reproduce plates on both sides of a leaf is perhaps a matter of opinion, but the saving of less than half a score of pages is hardly compensated by placing some illustrations right away from their context as for example inserting the beautiful coloured plate of dysenteric lesions of the intestine in the pellagra section. The two pellagra plates could have been placed together and the dysentery one separate instead of one pellagra plate by itself and the other with the dysentery plate. Again the radiograph of calcified cysticerci comes in the guinea-worm section.

The part dealing with Food is a good summary of a difficult subject. Tropical anaemias are interestingly described but one fails to find reference to the pallor wrongly spoken of as tropical anaemia where there is no true anaemia. The risk of cooling drinks by addition of ice is not mentioned, though it is often done and may be a very serious risk. There is a peculiar slip on p. 29 which might be designated an accident of accident and another on p. 117 where γ is said to be equal to 0.0001 gm. γ = one-millionth of a gramme or 0.001 mgm. On p. 105 in Fig. 145 the male and female *W. bancrofti* have been transposed the formula of thiobismol (p. 52) needs a little correction.

The malaria section is one of those which have practically been re-written that on yellow fever is another. The list of malaria vectors has been both revised and much enlarged and there is also included a list of the regions of their typical breeding places. The typhus table has been remodelled and brought up to date the text here has been to a great extent re-written and now includes Lone-star (Bohls) fever and the account of the Q fever of Queensland is much fuller. The vitamin chapter has been expanded and almost entirely re-written. The inclusion of a table of syndromes characterized by glossitis and stomatitis was a happy thought. Other useful additions to which special attention should be directed are the improvement of the *Glossitis* table by

accompanying drawings of their distinguishing characteristics most informative also is the summary of the present state of trypanosomiasis in different parts of Africa, a short section on tick borne encephalitis has been added (p 618) A very valuable addition is the section on Technique of Injections Blood-transfusions etc already alluded to This is separate from the one on Laboratory Technique staining methods etc. usually included under the term Clinical Pathology

May we with all deference offer a suggestion or two for the Editor's consideration? It is a little difficult to understand the reason for including forms of anaemia gonorrhoea diabetes pulmonary tuberculosis gout zymotic diseases goitre and malignant growths in a chapter on Life in the Tropics The forms of anaemia met with are important enough to warrant a separate chapter and we venture to suggest that the two excellent opening chapters might end at the middle of p 30 and a third introductory chapter be inserted on General Diseases of Temperate Climates as modified in the Tropics Next mention might be made of paralytic accidents in the treatment of rabies more stress might be laid on the differences rather than on the similarities between tropical eosinophilia and Loeffler's syndrome the risk of confusing the Lentz bodies of distemper in dogs with the Negri bodies of rabies—and the so-called hysterical form of distemper may resemble rabies—and hence dispensing with inoculation for determining the diagnosis of the latter the use of carbolic (Lifebuoy) soap emulsion obtainable almost anywhere in delaying the action of snake venom and so enabling time to be gained for obtaining the necessary antivenene Lastly the Appendix Section A, should be designated Medical Zoology because it includes three subsections Protozoology Helminthology and Entomology As it is the whole section is named Medical Protozoology which incidentally has been rearranged, and in it are included the two latter The designation was better in this respect in the previous edition

In conclusion those who possess the eleventh edition are strongly advised to purchase this the twelfth, because it is almost a new work, for the changes are many and important and no one who intends to keep up with the times can afford to be without it. Also now that men are returning from service abroad a proportion of them suffering from or harbouring the seeds of tropical disease the general practitioner at home can no longer take up the attitude that such diseases do not interest him and are beyond his purview and he too should read this book with care and keep it on his shelf.

To review the new *Manson* has been a privilege a *πρόνος ἀπονοή*—a true labour of love—and the Editor is to be heartily congratulated on the successful accomplishment of a Herculean task. *Manson* remains the best one-volume work on tropical medicine in English and probably in any language

H Harold Scott

PEREIRA O de Loloia. Contribuição ao Estudo do Tratamento da Lepra segundo os resultados obtidos em 10 anos de Terapêutica Antileprotica na Leprosaria Central de Goa. [The Treatment of Leprosy and its Results at the Central Leprosarium at Goa.] *Supplement No 2 to An Inst Med Trop* Lisbon. 1945 Nov 147 pp 1 fig [246 refs.]

The author of this record has tried to convey so much information in a small space that the whole is condensed to such a degree as to be almost a catalogue His original proposition was to write three separate works —(1) Preparatory treatment of leprosy (2) Treatment of leprosy itself (3) Treatment of the complications of leprosy In the present publication the two first are dealt with presumably the third will come later All his statements are amply documented by references to the work and reports of others A list of 246

progress in all the important tropical diseases which epitomize the abstracts made in the *Tropical Diseases Bulletin* on the several subjects during that year.

There is hardly need to review in full a work of such popularity as this. Its usefulness is obvious in the fact that a new edition has been called for every 4-5 years since it first saw the light and that, in addition, it has been reprinted no less than 17 times. Since the last edition was published in 1940 several matters which were then *sub judice* or obscure have been decided or solved necessitating modification in presentment. accompanying drawings of their distinguishing characteristics most informative also is the summary of the present state of trypanosomiasis in different parts of Africa, a short section on tick borne encephalitis has been added (p. 618). A very valuable addition is the section on Technique of Injections Blood transfusions etc. already alluded to. This is separate from the one on Laboratory Technique staining methods etc. usually included under the term Clinical Pathology.

May we with all deference offer a suggestion or two for the Editor's consideration? It is a little difficult to understand the reason for including forms of anaemia gonorrhoea diabetes pulmonary tuberculosis gout zymotic diseases goitre and malignant growths in a chapter on Life in the Tropics. The forms of anaemia met with are important enough to warrant a separate chapter and we venture to suggest that the two excellent opening chapters might end at the middle of p. 30 and a third introductory chapter be inserted on General Diseases of Temperate Climates as modified in the Tropics. Next mention might be made of paralytic accidents in the treatment of rabies more stress might be laid on the differences rather than on the similarities between tropical eosinophilia and Loeffler's syndrome the risk of confusing the Lentz bodies of distemper in dogs with the Negri bodies of rabies—and the so-called hysterical form of distemper may resemble rabies—and hence dispensing with inoculation for determining the diagnosis of the latter the use of carbolic (Lifebuoy) soap emulsion obtainable almost anywhere in delaying the action of snake venom and so enabling time to be gained for obtaining the necessary antivenene. Lastly the Appendix Section A should be designated Medical Zoology because it includes three subsections Protozoology Helminthology and Entomology. As it is the whole section is named Medical Protozoology which incidentally has been rearranged, and in it are included the two latter. The designation was better in this respect in the previous edition.

In conclusion those who possess the eleventh edition are strongly advised to purchase this the twelfth because it is almost a new work for the changes are many and important and no one who intends to keep up with the times can afford to be without it. Also now that men are returning from service abroad a proportion of them suffering from or harbouring the seeds of tropical disease the general practitioner at home can no longer take up the attitude that such diseases do not interest him and are beyond his purview and he too should read this book with care and keep it on his shelf.

To review the new Manson has been a privilege a *νόμος ἀννομος*—a true labour of love—and the Editor is to be heartily congratulated on the successful accomplishment of a Herculean task. Manson remains the best one-volume work on tropical medicine in English and probably in any language.

PEREIRA O. de Lencastre. Contribuição ao Estudo do Tratamento da Leprosia segundo os resultados obtidos em 10 anos de Terapêutica Antileprotica na Leprosaria Central de Gôa. [The Treatment of Leprosy and its Results at the Central Leprosarium at Gôa.] Supplement No 2 to An. Inst. Med. Trop. Lisbon. 1945 Nov. 147 pp. 1 fig. [246 refs.]

The author of this record has tried to convey so much information in a small space that the whole is condensed to such a degree as to be almost a catalogue. His original proposition was to write three separate works—(1) Preparatory treatment of lepers (2) Treatment of leprosy itself (3) Treatment of the complications of leprosy. In the present publication the two first are dealt with presumably the third will come later. All his statements are amply documented by references to the work and reports of others. A list of 246

references to writers of all nationalities is given and more than half (129) are to abstracts which have appeared in the *Tropical Diseases Bulletin* indicating how useful foreign writers find this publication.

In the first part which occupies one-third of the thesis the preparatory treatment is considered and discussed, attention being drawn to obtaining the hearty co-operation of the patient seeing to his food and nutrition to his physical exercise his mental occupation and distractions, and the treatment of concomitant or intercurrent disease, such as malaria scabies influenza etc.

The Central Leprosarium of Gôa (India) was opened in May 1932, in a fairly isolated rural spot, Macasana in the Salcete Municipality and it is divided into two parts one occupied by the lepers the other by the staff their families and dependants. At present there are 100 resident patients. In 1935 there was an outbreak of malaria and 34 of the lepers were attacked. — The malaria did not seem to affect the leprotic infection in any way nor *vice versa*. Twenty four received vaccination against smallpox and in 15 of them the small operation was followed by a leprotic reaction—aggravation of lesions especially those of the nerves and the nodules and glands swelled—which led to much debility and prolonged time of convalescence in half the patients the vaccinia pustule became an ulcer which in some cases took several weeks to heal this was specially noted in those who showed a marked leprous reaction.

In the second part the author considers the many forms of treatment tried in leprosy. He deals in turn with chaulmoogra, the oil and its derivatives its administration *per os per cutem* intramuscularly and by the blood-stream, the use of the whole oil and of its ethyl esters and of the combination of chaulmoogra with cholestern. Next with serum therapy Reenstierna's serum and antitetanus serum, with vaccine therapy vitamins, sulphonamides venoms, dyes and chemotherapy. Abundant quotations from the literature are given on each of these and then remarks on the cases in which the author has himself tried the method. The numbers are, as a rule, too small to be of any statistical value in gauging results but when added to those of others they may be of some value and anyway are an expression of the opinion of the author.

For oral administration refined chaulmoogra oil is given in gelatin capsules, containing 30 minims each. For the first week in each month one capsule daily is prescribed, for the second and third weeks two capsules daily for the fourth week none. The cutaneous route is objectionable because of the odour imparted to the body and clothes. Intramuscular injection is the favourite mode of administration and three cases are quoted one received 33 injections in seven months, when death took place by which time the leprosy had slightly improved. A second had only two injections when the onset of cardiac disturbances necessitated a stop the third had 25 injections and was slightly improved. For ethyl ester injections the author used E.C.C.O—ethyl esters of the oil of *B. wightiana* 1 cc., camphor 1 gr. doubly distilled creosote 1 cc. and olive oil 2.5 cc. This is the method chiefly used in the Gôa leprosarium. Three cases are quoted one man received 377 injections and then died. The drug had no effect on his disease. A second received 23 injections in 4½ months, together with Moogrol and was "clinically cured, but was continuing treatment a third was treated similarly and had improved. Sixty two patients were treated with intravenous injections (up to 70 injections) of Alepol 11 of them improved, 5 became worse and 46 remained in their original state.

Ten lepers were given the Reenstierna serum in three or four series of 2-3 intramuscular injections with 5-10-week intervals between the series. The injections were followed by considerable physical depression in all three, improved, one was worse and six remained unaffected.

One case is recorded of a patient who developed symptoms of tetanus trismus convulsions opisthotonus etc. and was given antitetanus serum. To the author's surprise the leprosy nodules shrank the infiltrations and anaesthetic patches diminished and ulcers cicatrized. [It is a pity that this serum was not tried in other cases to confirm or refute whether this was purely incidental.]

Eleven were given Vaudremer's vaccine subcutaneously in increasing doses and good effects were observed in those with oedematous infiltration of hands and feet with elevation of temperature and general weakness for those with eye lesions special caution is to be exercised in its use. Betaxan was found to benefit those with polyneuritis and joint pains in eight patients Sulphonamide drugs were tried in a few cases but did not seem to bring about any amelioration. For animal venom the toad (*Bufo bufo*) was tried on some cases of nodular leprosy no benefit resulted. The dyes used for treatment were methylene blue (1 per cent. in distilled water starting with 5 cc. and gradually increasing till 35 cc. might be given at one time) brilliant green crystal violet trypan blue fluorescein eosin resorcin gentian violet erythrosin fuchsin acridin methyl green among others the numbers of cases so treated are not stated but the statement is made that amelioration followed in several

The author sums up his opinion in the following paragraphs Chaulmoogra gives the most certain results it is best administered in the form of the pure oil neutralized good results were also obtained with Leprosan a product of Taraktogenol A Alepol was generally disappointing but seemed to do most good in those of mixed type with skin lesions prominent a mixture of chaulmoogra and cholesterol injected intravenously is well tolerated but the practical result is doubtful Reenstierna serum proved best in rhinitis cases and those with anaesthetic and infiltrated areas Vaudremer's vaccine is specially indicated for those with oedematous infiltrations of the extremities toad venom was good in leprosy adenitis and neuralgias in which benefit was often prompt sulphonamide drugs find no place in the treatment of leprosy Vitamin B₁ benefits those with neuralgias and joint pains methylene blue caused disappearance of large dyschromic blotches but had no effect on a nodular case mercurochrome intravenously was of benefit in lepromatous ulcers.

MOOSER, Hermann. [Professor an der Universität Zurich.] Die Beziehungen des murinen Fleckfiebers zum klassischen Fleckfieber [The Relationship of the Murine Typhus Fevers to Classical Typhus.] *Acta Tropica* Basel. 1945 Suppl. 4. 87 pp 1 pl. & 1 chart. [171 refs.]

In this volume of 87 pages including a bibliography of 171 references the author recapitulates his reasons for holding the following views —(1) Contrary to the opinion of NICOLLE there is only one murine typhus (2) The differences between *Rickettsia prowazeki* and *R. mooseri* are quantitative and not qualitative. (3) These differences however are regularly observed and must be regarded as specific.

The quantitative differences are regarded as being heterologous protection with vaccines scrotal phenomenon in the guineapig pathogenicity for white mice and serial transfer in mice and rats In these respects there is merely a disproportion between the pathogenicity and serological activity of the two strains Some strains of classic typhus cause scrotal lesions in guineapigs and some can be transferred in series through white mice when large doses of infecting material are used.

Contrary to the claims of NICOLLE and GIROUD *R. mooseri* develops in lice exactly as does *R. prowazeki* and there is no difference between the two with respect to their multiplication in fleas.

[June, 1946]

The assumption that classical typhus has originated from murine typhus remains an unproved hypothesis and those who refuse to accept this hypothesis can choose between ZINSSER'S view that infection is carried over in inter-epidemic periods by late relapses and the assumption of Polish workers that the carry-over is by dried faeces of infected lice. Nicolle's hypothesis of a carry-over by inapparent infection is regarded as having been disproved by the author's work in Mexico.

The author again suggests that fleas may play a part in maintaining *R. prowazeki* outside the human body and so in maintaining infection during inter-epidemic periods. In support of this view are the facts that the organism multiplies just as readily in fleas as does *R. mooseri* and that the life span of the fleas is not shortened by the infection.

Great stress is laid on the importance of the work done by the author and his colleagues in Mexico in throwing light on the significance of the rickettsiae bodies which are stated to have been of a doubtful nature till 1931. [It seems surprising that serious doubts could have been entertained on this subject after the appearance of the classical work of VOLLMANN and his colleagues (see this Bulletin 1922, v 19 448) in and before 1922.]

The author claims that much of the recent work on the rickettsiae is merely a rediscovery of the findings made earlier in Mexico and the U.S.A.

The general tone of the book is sharply critical especially of Nicolle and Zinsser who unhappily are dead. But although this unfortunate circumstance puts the author in an invidious position, he cannot be blamed for speaking plainly in the interests of what he regards as scientific truth. A disturbing impression conveyed by the book is that some widely accepted generalizations connected with epidemic and murine typhus are shown to have been based on inadequate and slender evidence.

No reference is made to the important recent work on the complement-fixation and rickettsiae-agglutination reactions in epidemic and murine typhus but this could hardly be expected in a book which consists largely of a vindication of the author's work about whose importance there can be no dispute.

John W. D. Aleson

WAR DEPARTMENT WASHINGTON Insect and Rodent Control. Repairs and Utilities. War Dept. Technical Manual TM 5-632 Wash. 1943 Oct. pp. iii+135 108 figs. [Numerous refs.]

This publication of the United States War Department is of quarto size printed in large type on good paper and is profusely illustrated with photographs and diagrams. Short descriptions of the chief insect and rodent pests and of the various methods of controlling them are given. The insect pests include mosquitoes house flies bed-bugs lice fleas ticks, chiggers (mites) termites (white ants) cockroaches beetles and ants. The rodents are rats mice ground squirrels and pocket gophers. moles coyotes and foxes are also mentioned.

The methods of control described and illustrated are the recognized major and minor sanitary measures—drainage screening spraying and oiling trapping, poisoning, fumigation and the protection of buildings against rodents and termites.

Emphasis is laid on the importance of co-operation of Army Departments—Medical, the Corps of Engineers and the Quartermaster Corps with each other and with the specialists of the Public Health Services the Navy Department, the Department of Agriculture and the Department of the Interior.

The book will be interesting and valuable to all who come into contact with these pests as well as those whose duty it is to deal with them.

[No. 7]

THE TREATMENT OF AMOEBIASIS

A REVIEW

By A. R. D. ADAMS M.D. Ch.B. M.R.C.P. D.T.M.

Emetine

The specific treatment of amoebic dysentery dates back some three centuries when ipecacuanha was introduced to Europe from South America as a remedy for dysentery. The employment of the drug was at first entirely empirical and it was not until 1912 that ROGERS [this *Bulletin* 1912 v 1 176] showed that the alkaloid emetine exerts a potent action on *Entamoeba histolytica* which had been recognized by SCHAUDINN in 1903 as the causative parasite of amoebic dysentery. The treatment of amoebiasis was thereafter established on a more rational basis and emetine in one form or another has since been recognized as an essential component of any course of treatment for the acute clinical manifestations of *E. histolytica* infections.

From the time of these early experiments it has been known that emetine alone will not cure that is completely eradicate more than a relatively small proportion of *E. histolytica* infections of the large intestine. What this proportion is has been the subject of some discussion: it is generally agreed to be not more than one third of those so treated (CRAIG: Amoebiasis and Amoebic Dysentery 1934 (London: Baillière Tindall & Cox p. 276) puts the figure at between 10 and 15 per cent.) but there is room for a more precise evaluation of the drug as a curative agent if given in full dosage during primary clinical attacks of amoebic dysentery. The view is now widely held that the use of injections of emetine in intestinal amoebiasis should be confined to the arrest of acute manifestations and that when these have been controlled the emetine injections should be stopped: it is considered pointless to continue them indefinitely or until a specified number have been given as a routine. One injection each day for 4 or 5 days will usually achieve the desired result and 12 injections will do no more. The salt of emetine employed for intramuscular or hypodermic injection is the hydrochloride and the dosage is 1 grain daily for an adult: this dose may be divided $\frac{1}{2}$ gr. being given at intervals of 12 hours but there is no obvious material advantage in this procedure. A patient receiving emetine injections should be confined to bed. Gross toxic effects are rarely seen from the use of the drug in normal dosage if it is not continued for more than 10-12 days. The toxic manifestations to be watched for in practice are a rising pulse rate, irregularity in the heart's action and a fall in blood pressure. If these develop the drug must be stopped. Peripheral

neuntia, with wrist and foot-drop and even death may occur but these are rarely encountered except when the dosage has been injudicious and the course unduly prolonged. Emetine should never be given intravenously.

Metastatic Infections

In addition to their rapid action in controlling acute clinical exacerbations of amoebiasis due to primary infection in the gut, emetine hydrochloride injections act specifically in arresting and in most cases in eradicating secondary amoebic infections in other organs and tissues, provided that treatment is not unduly delayed. In liver infections the parasites are usually destroyed by one course of a dozen daily injections of emetine hydrochloride and this is equally true of infections of the lung, of the skin, and of those direct extensions of the infection from intestinal lesions to neighbouring organs and structures which result in the formation of amoebic granulomata (amoebomata) in the abdomen. Where such diffusions of the infection from the primary focus in the large bowel occur a course of 12 injections of emetine one a day should therefore be given at once to kill the amoebae in the secondary lesions. Surgical intervention may also be necessary but this can usually be averted if the condition has not been allowed to develop too far before the emetine is administered. It is wise to adopt a conservative attitude to surgery and to await developments before deciding on operative interference. remarkably large amoebic liver abscesses, so long as they are bacteriologically sterile, are often absorbed when the causative parasites have been destroyed by emetine treatment. Where evacuation of an amoebic liver abscess is deemed necessary open drainage of the cavity is now generally held to be preferable to aspiration the latter usually has to be repeated, and often proves inadequate, so delaying the more radical procedure. In no case where surgery is resorted to must the fundamental sterilization of the lesion by parenteral emetine injections be overlooked or the erosive process will continue and the parasitic infection will extend into the tissues involved in the operation. There is no point in putting emetine into the abscess cavity where it acts as a local irritant and does not appear to reach the tissues infiltrated with parasites around the lesion. Where such secondary infections with *E. histolytica* occur it must never be forgotten that the primary infection is in the large intestine and that the successful treatment of the secondary lesion leaves this primary infection, in most cases, unaffected.

Treatment of the Intestinal Infection.

The eradication of an *E. histolytica* intestinal infection, whether the patient be harbouring a symptomless infection, and passing formed stools containing the cystic form of the parasite, or be suffering from recurring frank amoebic dysenteric attacks with the passage of blood and mucus, containing the vegetative stage of the parasite is in general, easy of achievement. A number of drugs administered by the mouth or in the form of colonic retention enemata, are employed for the purpose, although none of these can be claimed as entirely specific, in that each given alone fails to cure a considerable proportion of cases. It is a common practice, in view of this, to use several drugs concurrently or in sequence, in the belief that their combined action is greater than that of any single one of the series, and the "combined treatments" of various authors [this *Bulletin* 1945 v. 42, 559-731 695 and 699] are the result. These treatments, broadly have much in common and in most cases of latent amoebiasis, and of early previously untreated relapsing amoebic dysentery are all effective in eradicating the infections. There seems to be no substantial evidence that any one of the courses is greatly superior to the others, provided that the

drugs are given so that they are liberated and retained for an adequate time in the correct part of the gut. MANSON, BAHR [this *Bulletin* 1945 v. 42 207] directs attention to the importance of the selection of drugs in a suitable form and of their proper administration in order to obtain satisfactory results. The drugs usually employed consist of an emetine preparation for oral administration (emetine-bismuth-iodide Auremetine) a trivalent arsenical similarly given (Stovarsol Carbarsone) and one of the iodo-oxy-quinoline series (Diodoquin Enterovioform Chiniofon) for oral use or as a colonic retention enema.

Toxic complications sometimes result from the administration of the arsenicals to susceptible individuals which usually at first take the form of skin eruptions and reduction in the dosage or withdrawal of the drug will arrest the trouble. Very occasional deaths have been recorded from arsenical poisoning may occur if the drugs are continued, grosser manifestation of arsenical poisoning may occur the arsenicals and even of Carbarsone which is usually regarded as the least toxic of them [MAYER *Lancet* 1946 April 27th 631].

For the treatment of a symptomless carrier of the infection the procedure would consist of the administration of one of the combined courses referred to above. For the treatment of an early uncomplicated and previously untreated case of relapsing amoebic dysentery seen during an acute exacerbation of the disease the procedure would be the administration of emetine injections for three or four consecutive days to arrest the clinical attack immediately followed by a combined course to eradicate the infection. In a case of amoebiasis complicated by a secondary lesion such as early embolic infection of the liver twelve daily injections of emetine would be given to sterilize the liver lesions and a combined course of treatment to sterilize the gut necessary the combined treatment of the intestinal infection might well be delayed after completion of the emetine injection course until the patient was convalescent from the operation but there should be no undue waste of time in tackling the intestinal focus.

Criterion of Cure

The criterion of cure of an intestinal *E. histolytica* infection is the continued complete absence of parasites from the stools after treatment. For a week or two after unsuccessful intensive treatment parasites will probably be too few in number in the stools to be found microscopically. Stool examinations should therefore be deferred for a couple of weeks after conclusion of the treatment and at least a dozen specimens taken on consecutive days should then be searched for parasites. If this search is competently made and no *E. histolytica* is found, the presumption of cure is considerable though not absolute. Certain cases of persistent infection may escape notice and where possible in order not to miss these serial stools should subsequently be examined at intervals over a period of at least twelve months.

Refractory Cases

During recent years a considerable number of men were invalided from the various war fronts in the East with severe relapsing amoebic dysentery which had yielded only temporarily to the treatments available under fighting conditions. Many of these men had received very large numbers (100 or more) of injections of emetine hydrochloride and some had in addition been treated with the arsenical or iodo-oxy-quinoline series of drugs. Some of these cases proved refractory to any of the combined courses of treatment referred to above even after repetition on several occasions although they temporarily

benefited from them in that the clinical manifestations of their dysentery abated, the intestinal infection was not cured, and clinical exacerbations of dysentery recurred, usually in severe form within a few days or a week or two of completion of the course. Such cases it is held by some workers had developed resistance to emetine as a result of the undue amount of this drug given them while in the field but while there is some clinical evidence that emetine-resistance may occur in individual cases of amoebic dysentery the development of emetine-fastness in a strain of *E. histolytica* has not yet been conclusively demonstrated *in vivo* or *in vitro* and its existence is still subject to proof. Nevertheless it is probably sound policy to assume that it may occur and to forestall it by avoiding prodigal and needless resort to emetine injections in the treatment of amoebic dysentery.

Associated Bacterial Infection of the Bowel Wall

Another explanation of the difficulty experienced in sterilizing some chronic relapsing amoebic dysenterics of their parasites is the establishment of an extensive concurrent bacterial infection of the tissues of the gut wall. On microscopical examination of the stools of such individuals pus will usually be found, and on sigmoidoscopy ulceration and a generalized inflammatory condition of the mucosa may be seen. A secondary bacterial colitis is coincident with the primary amoebiasis and thus concomitant bacterial colitis probably renders the amoebic dysenteric infection more difficult to eradicate. The colitis not infrequently persists as a chronic post-dysenteric colitis after the successful eradication of the amoebic infection. That its presence makes the amoebiasis more resistant to treatment is to some extent substantiated by the experience of certain workers who either prior to or concurrently with, a combined course of treatment for the intestinal amoebiasis now give a therapeutic course of one of the sulphonamide drugs (sulphaguanidine succinyl sulphathiazole or phthalyl sulphathiazole) or of penicillin in massive dosage or of both with improvement in the cure-rates for the amoebiasis in such cases. When a patient has proved refractory to previous treatment or has suffered for long from an untreated relapsing amoebiasis, or when pus is found in the stools or there is sigmoidoscopic evidence of a diffuse inflammatory or ulcerative condition of the large bowel such preliminary treatment with a sulphonamide drug or penicillin or both, is advisable. HARGREAVES [this *Bulletin* 1945 v. 42, 559-595] has claimed very good results with an initial dose of 100 000 units of penicillin intramuscularly followed by 33 000 units every 3 hours to a total of one or two million units and succinyl sulphathiazole to a total of 80 gm. by the mouth. The writer's practice is to give succinyl or phthalyl sulphathiazole and Chinofon each by the mouth, on alternate days for ten days prior to combined therapy in such cases and he has not found penicillin so generally effective as has Hargreaves in relieving or arresting a severe bacillary colitis. It is to be clearly understood that the sulphonamides and penicillin have no direct action on the amoebae their action is exerted on the secondary bacterial invaders. Nevertheless evidence accumulates that control of a gross secondary bacterial invasion of the wall of the large intestine leads to more effective action of any treatment directed against the *E. histolytica* infection.

Diet and Management.

There is general agreement also that a liberal nutritious, easily assimilable and palatable diet is of benefit in these cases, and that adjuvants in the form of vitamin concentrates may play a part in promoting bodily resistance. Whether confinement to bed throughout combined treatment is necessary or desirable must be determined by the circumstances of each individual case.

Complicating infections should be dealt with and the general condition be maintained at as high a level as possible. Abstinence from the bulkier alcoholic drinks is advisable and the maintenance of the morale of patients suffering from such a disease is an important factor in their successful treatment, as willing co-operation is of fundamental importance to its achievement.

Finally when the amoebiasis has been successfully eradicated, any troublesome sequelae such as the haemorrhoids commonly found in association with a diarrhoeic disorder must receive attention before the patient is discharged as cured.

SUMMARY OF RECENT ABSTRACTS *

VI PLAGUE.

Epidemiology Transmission

In *Public Health Reports* (p 32) is a record of the only human case of plague notified in the United States during 1943. This case in a child aged two was unusual in that death took place two months after onset and was due to bubonic plague with chronic plague encephalitis. Plague is widespread in rodents in the United States.

In the *Epidemiological Information Bulletin* of the Health Division of UNRRA (p 724) there is an account of an outbreak of plague in Western Yunnan near the Burma frontier where plague has long been endemic. Most of the patients had received one or more inoculations of vaccine but though this had not been enough to prevent infection the death rate in the vaccinated was much lower than in the non vaccinated [see also MÜNTER below]. Sulphadiazine in a small series of cases appeared to give better therapeutic results than sulphathiazole or serum.

SHIH and POLLITZER (p 725) have calculated the point at which the incidence of plague in the rat population of central China becomes a serious threat to man. They have found that the situation is reassuring so long as the incidence of infected rats is well below 20 per cent but human plague is imminent if a level of 25 per cent is reached.

POLLITZER and LI (p. 726) discuss the decline of epidemics of pneumonic plague in China. The principal factor seems to be the diminishing incidence of cases with cough and bloody sputum teeming with bacilli. The danger of infection from patients with plague pneumonia but without bloody sputum is much less than from those with the classical signs.

LE GALL (p 290) contributes an account of plague in Madagascar making the point that the incidence rose to a high level about 1932 and fell rapidly after the institution of vaccination on a large scale, with the live EV vaccine. Pneumonic plague is common in the high plateau region and is a respiratory disease of direct transmission. For bubonic plague *X. cheopis* is the usual vector and this flea can live for some time away from rats for this reason the rat flea index is not now regarded as important in epidemiological studies. Continued examination of captured rats for plague infection seems now to be superfluous in Madagascar. Treatment with EV anti-plague serum and sulphonamides gives good results in bubonic plague but not in the pneumonic infection.

The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1945 v 42. References to the abstracts are given under the names of the authors quoted and the page on which the abstracts are printed.

BLANC and BALLAZARD (p. 33) quote an experiment which, in their view tends to discredit the theory that blocking of infected fleas is an important factor in the transmission of plague. A group of *Xenopsylla cheopis* were infected, and remained infective during a span of life which did not differ from the normal. If transmission is a function of blocking, and if, as is usually supposed, a blocked flea does not live long, it would appear that the fleas became blocked successively which is unlikely. The authors think, rather, that the principal factor in transmission is the multiplication of bacilli in fresh blood taken up in frequent feeds. An infected flea, after a fast of 15 days, is unable to infect by its first bite, but becomes infective less than 12 hours later. This view is supported by experiments on other arthropods in which blocking does not occur. It has a bearing on human plague, since *X. cheopis* attacks man only when urged by hunger. The same authors (this Bulletin 1944 v. 41: 281) maintain that, in Morocco transmission of plague from man to man by *Pulex irritans* is by no means uncommon. GIRARD (p. 375) discusses this question, and concludes that although the prevalence of *P. irritans* may create special infective conditions in Morocco the really important vector in general is *X. cheopis*. He upholds the view that blockage of the proventriculus, which occurs in *X. cheopis* but not in *P. irritans*, is an important factor in transmission.

Girard makes the point that *X. cheopis* may exist for long periods away from the rat (see LE GALL above) and emphasizes the overriding importance of eliminating contact between rat and man, in the control of plague. In reply to Girard, BLANC and BALLAZARD (p. 376) uphold the two propositions that the human flea and louse usually become infected on man in the agonal period, and that they can transmit plague. They point out that *P. irritans* is strikingly averse to biting guinea-pigs, and that this fact has vitiated much laboratory experimental work—it will, however, bite man freely.

HECHT (p. 281) has shown that although in part of Venezuela *Rhopalosiphum* is usually the most common flea on trapped rodents, there is from time to time a considerable increase in the proportions of *X. cheopis* and *X. brasiliensis* caught.

JELLINEK (p. 805) records the host relationships and geographical distribution of fleas of the genus *Oreopsylla* in North America.

In a survey of sylvatic plague in part of Argentine SAVINO and KUSNETZ GORAN (pp. 33-465) found natural infection in *Graomys griseoflavus centralis* which is known to have contacts with human habitations, and in several cats.

SAVINO *et al.* (p. 555) describe a chronic encapsulated abscess, containing living plague bacilli, in the spleen of a rat. This is a very rare condition, and may indicate the means by which infection is carried over from one plague season to the next.

Pathology

MACCIELAVELLO and UNGER (p. 466) think that although invasive capacity and toxicity of *P. pestis* are to some extent interdependent, they may differ quantitatively. Strains from the Andean region of Ecuador are highly invasive, belong to the S and not to the R form, are of relatively low toxicity and are peculiarly pneumotropic. It seems that the very mildness of plague in that region allows time for the production of secondary pneumonic plague, to a greater extent than elsewhere.

DEVISAR (p. 896) reports a sudden chromogenic dissociation, perhaps even a mutation, giving colonies of typical R and S type, with yellowish coloration, in the E.V. strain of the 104th passage.

WOODWARD (p. 281) has shown that *P. pestis* has an action in decomposing the ribonucleic acid of yeast.

Treatment

A case of laboratory infection with plague is reported from San Francisco (p 33) [this is presumably the case referred to by MÜNTER, below]

Recovery from primary pneumonic plague is very rare. MÜNTER (p 805) reports the case of a doctor in the United States who was engaged on plague investigation and who about one year before he contracted plague pneumonia had received five injections of plague vaccine. The diagnosis of plague pneumonia was completely established, and treatment with sulphadiazine was instituted at an early stage the patient recovered and the very careful precautions taken to prevent spread of the disease to those who attended him were entirely successful. The author makes the point that recovery cannot be attributed solely to the action of the drug since other factors e.g. the vaccination may have contributed to the favourable result [see the UNRRA report above]

In an alternate-case trial of sulphadiazine and sulphathiazole in plague in an adequate series of patients WAGLE (p. 558) has shown that though each drug is valuable sulphadiazine is considerably more effective than sulphathiazole the case mortality rates in the two series were 21.9 and 33.7 per cent. respectively when no differentiation was made between septicaemic and non-septicaemic cases and 12 and 21 per cent when patients moribund on admission were excluded. The dosage for sulphadiazine was 10 gm the first day, and 6 gm on subsequent days. DE VILLAFANE LASTRA (p 892) treated 35 patients (four of whom had septicaemic plague) with sulphathiazole in high dosage 10-12 gm. daily for adults giving a blood level of over 8 mgm. per 100 cc. for not less than 6 days. There were five deaths all in patients with bubonic plague and in four of these plague meningitis was present.

The case mortality rate from plague in part of Hawaii between 1910 and 1944 was almost 100 per cent compared with 49 and 32 per cent in San Francisco and New Orleans. WITLIN and WILBAR (p 642) therefore investigated the therapeutic effect of penicillin experimentally in Hawaii all the guinea-pigs died and the result was wholly disappointing.

MACKAY DICK (p 377) notes a series of severe urticarial reactions in British soldiers who received injections of anti plague serum none of the Indians similarly treated showed this effect.

Control Vaccination

HUNDLEY and NAST (p 282) recall that plague was found in Tacoma in rats for the first time in 1942. An intensive campaign was undertaken and so far as can be determined the infection was brought under complete control at a reasonable cost. The measures included trapping poisoning gassing fumigation food sanitation harbourage elimination rat proofing quarantine and educational activities. SHIH *et al* (p 726) describe the measures taken to control plague in two small towns in China.

In an investigation into the immunizing power of living attenuated vaccines in plague HSUE (p 726) concludes from animal experiments—that dead vaccines are unsatisfactory that attenuation of virulent bacilli can be effected by continual subculture at 41-42°C. that a spontaneously attenuated strain had much better immunizing power than artificially attenuated strains and that antigenic potency of living vaccines is higher the further they diffuse into the internal organs from the site of injection.

ABRAMOVA (p 642) shows that vaccination with an avirulent live strain of *P. pestis* causes an increase in the opsonic index of animals but in his experiments correspondence between the degree of immunity as tested by subsequent virulent inoculation and the opsonic index was not exact.

It has long been known that guinea-pigs rendered partly but not completely resistant to plague by injection of vaccine or immune serum are especially liable to death from secondary plague pneumonia after virulent infection. GIRARD (p. 377) raises the question whether the prevalence of pneumonic plague in Madagascar can be explained by some such mechanism the result of the extensive use of live E.V. vaccine and whether a state of incomplete immunity could restore the virulence of the living organisms of which the vaccine is composed. He answers these questions in the negative, showing that pulmonary complications are not more common in the vaccinated than in the unvaccinated, and that the incidence of pneumonic plague has diminished in Madagascar *pari passu* with the total incidence of all forms of plague. Man, therefore appears to differ from the small rodents in liability to plague pneumonia after insufficient immunization. *Charles W. Wilcocks*

BRIERLEY, W. B. Malaria and Socio-Economic Conditions in Mississippi. Reprinted from *Social Forces* 1945 May, v. 23 No. 4 451-9. 4 graphs.

In establishing a definite relationship between socio-economic conditions and malaria mortality from year to year in the State of Mississippi, the author deals with a neglected aspect of malaria epidemiology. The prosperity of Mississippi is mainly dependent upon cotton cultivation. Cotton tenant farmers are among the poorest farmers in the United States—in many areas they live at subsistence level, their existence depending upon the price of a single commodity. The cotton-growing areas have an inadequate supply of food crops and their inhabitants live on a meagre and ill-balanced diet. There is a definite relationship between the price of cotton (retarded for one year) and net return from personal income tax, and malaria mortality in the State from year to year. During years in which income is high the people have more and more varied food, their homes are kept in better repair especially in regard to screening, and if suffering from malaria they have money for medical services and adequate antimalarial drugs. During years of low income the reverse is the case.

About 950 000 people of the 3 100 000 population of Mississippi are in the tenant farmer group. They have nomadic habits—29 per cent. of them operate the same farm for only one year or less, then they move on in search of a better job. Eighty per cent. of all tenant farms are occupied by farmers who have been on the farm for less than five years. This mobility accounts in some measure for the low socio-economic level.

In Mississippi socio-economic conditions appear to explain adequately the cyclic exacerbations of malaria every five, six or more years which have characterized the disease in the southern United States. *Norman White*

BRIERLY W B The Influence of Surface Features upon the Distribution of Malaria in Northwestern Mississippi. Reprinted from *J Geography* 1945 Nov v 44 No 8 312-24 3 figs

The influence of physiographic conditions in determining variations in malaria incidence is well illustrated in this study. The delta region in north west Mississippi is a flat monotonous plain. It slopes only four or five inches to the mile southward and eastward and contains innumerable swamps and other collections of water favourable for the breeding of *Anopheles quadrimaculatus*. The Loess Bluff Upland which borders the delta region to the east is a rough rolling hilly area with relatively few hydrographic features. Malaria is much more prevalent in the delta

LE GAC P SEITE P & COMBES OT DE MARSAGUET G Étude sur le paludisme à Ouagadougou (Study of Malaria in Wagadugu.) *Bull Soc. Path Exot* 1945 v 38 Nos. 7-8 201-16 1 fig

A severe outbreak of malaria in Wagadugu at the close of 1941 and the beginning of 1942 prompted the malaria survey, the results of which are here recorded. (Wagadugu is the capital of Mossi in French West Africa just north of the Gold Coast Colony.)

An examination of 2 942 children from 2 to 12 years of age during the rainy season June to October revealed a spleen rate of 37.15 and a parasite rate of 53.67 per cent. The corresponding rates for 808 children in 7 adjacent villages were 44.55 and 50.49 per cent. The gametocyte rates of these two groups of children were 14.81 and 22.76 per cent. *P. falciparum* was responsible for 93 per cent of infections the remainder being due to *P. vivax*. *P. malariae* was not found.

Three species of *Anopheles* were found *A. gambiae*, *A. funestus* and *A. nili*. *A. gambiae* is much the most prevalent. Marigots constitute the chief breeding places. (A marigot is a river that loses itself in the ground often dry in the dry season it is subject to flood in the rains.) In Wagadugu certain of the marigots are dammed so as to contain water throughout the year. The laterite soil favours the creation of temporary breeding places suitable for *A. gambiae* breeding. Of anopheline breeding in marigots only 5 to 6 per cent. are *A. funestus* the remainder being *A. gambiae*. *A. nili* breeds in wells in which 72 per cent of the anopheline larvae taken were of this species. In Wagadugu there are some 1 880 wells never more than 10 to 12 metres in depth and generally dry for two or three months in the year. Anopheline larvae were found in 452 of the 1 880 wells examined. Wells dug or drilled to a greater depth, tapping an underlying sandy stratum are capable of supplying abundant pure water all the year round and would obviate the necessity of relying on marigots for the supply as hitherto.

The very great scarcity of oils for use as larvicides contributed to the exceptional severity of malaria in 1941-42

RIBBANDS C R Moonlight and House-Haunting Habits of Female Anophelines in West Africa. *Bull Entom Res* 1946 Feb v 36 Pt. 4 395-415 3 figs [13 refs.]

The experiments were carried out in a village near Freetown Sierra Leone and at Krabonekrom, near Sekondi, Gold Coast. The author throughout compares his findings in West Africa with those obtained by HADDOW [this *Bulletin* 1942 v 39 595] in Kenya. All catches were made by collecting mosquitoes after spraying the room with a pyrethrum-in-kerosene mixture. In order to avoid any repellent effect a series of identical huts were used and the human bait was shifted to a fresh house after each catch. Ribbands

considers that if this precaution is used the spray method is more efficient than the hand-catching employed by Haddow.

In West Africa, female anophelines were virtually absent from unoccupied huts. The author suggests that the higher proportion found in such huts in Kenya may be the result of outdoor conditions which in East Africa may be less favourable to adult anophelines. The great majority of *A. gambiae* and *A. funestus* which have fed in native houses remain there until after dawn, the period which elapses after dawn before they finally leave the hut depends on the extent to which the interior of the hut is exposed to daylight. *A. melas* seldom left huts in which they had fed, if there was little light or ventilation until after dark the following day.

As suggested by the title of the paper Ribbands devoted considerable attention to the influence of moonlight on the house-haunting habits of West African anophelines, a subject which, so far as the reviewer is aware has previously received but little attention. The results obtained proved a high degree of correlation between the time of moonlight and the time of entry of *A. funestus* the figures for *A. gambiae* were inadequate, but the author suspects that a similar relationship probably exists. The following is quoted from that part of his summary concerned with the effects of moonlight: "During moonless periods, the fighting of ♀ *A. funestus* was partially inhibited, and when the moon came out, the waiting mosquitos entered the huts in greatest numbers. The average proportion caught when the moon rose during catching periods ending 10 p.m., midnight and 7 a.m. was approximately 50 per cent., 100 per cent. and 400 per cent. greater respectively than the proportion caught during these periods on moonless nights. On moonless nights many mosquitos waited until twilight of the following evening before entering the huts, and in consequence the average proportion caught in the period ending 8 p.m. was six times greater on moonless nights than on the nights after full moon.

"The records for ♀ *A. melas* are less complete and the correlation coefficient for the relation between time of entry and time of moonlight has the value of 0.421 ± 0.184 a result which is barely significant. In view of the highly significant correlations found in the case of *A. funestus* it is unlikely that this correlation is fortuitous.

The author considers that in view of the high correlation which he has shown to exist between the time of moonlight and the time of fighting, it would be useless to compile records of the average time of entry into houses unless either the readings were sufficiently numerous to cancel out the effects of the lunar cycle or else weighted averages of percentage catches were used. With the latter method he obtained the following results:—

The average rate of entry of ♀ *A. funestus* throughout one complete lunar cycle at Krahonkrom Gold Coast, was 27 per cent. before 8 p.m., 22 between 8 p.m. and 10 p.m., 21 between 10 p.m. and midnight and 30 after midnight. The similar rates for *A. gambiae* (based on very few records) were 10, 20, 30 and 40 per cent. respectively. Comparable rates for *A. melas* in Sierra Leone are not available but at least 45 per cent. entered before 10 p.m. (=11 p.m. Gold Coast time).

As regards the time of feeding, Ribbands's observations show that in West Africa, anophelines usually rest on the wall of the hut for some little time before commencing their meal. Thus although 27 per cent. (figures based on *A. funestus*) of anophelines entered houses before 8 p.m., 58 per cent. of those caught at 8 p.m. were unfed whereas of the anophelines caught in huts after dawn, 95 per cent. were fully fed. The author points out that this may explain how residual DDT on walls is able to protect the occupants of the room against biting, since the mosquitoes are incapacitated during this preliminary short resting period.

[This is a most useful and interesting paper which should be consulted in the original by those concerned.]

ECKSTEIN A & NIXON W C W Congenital Malaria. *Brit Med J* 1946 Mar 23 432-3

With wide experience of malaria in Turkey the authors contend that congenital malaria is not uncommon in places where the disease is endemic. They cite five cases [The ages of these infants ranged from 2 to 3 weeks so the possibility of infection after birth cannot be altogether excluded though this seems to have been unlikely in some cases] All five mothers were suffering from malaria. Three were *P vivax* infections two *P falciparum*. One of the infant patients was one of twins the other twin also harboured *P vivax* but presented no clinical signs of infection other than some enlargement of the spleen. It is suggested that high infant mortality rates might be reduced if mothers received adequate suppressive and prophylactic treatment during pregnancy Norman White

MAKARI J G The Cephalin Flocculation Test in Malaria. *Brit. Med J* 1946 Feb 23 272-3 2 figs

The cephalin-cholesterol flocculation test was first described by HANGER (*Trans Amer Phys* 1933 v 53 148) and has since proved its value as a test of hepatic function. The author applied it in 105 cases of malaria. A positive flocculation reaction was obtained in 96 cases (91.4 per cent.) in 94 of these the reaction was ++ or above. Both *P falciparum* and *P vivax* infections were included. The reaction tended to become negative with anti-malaria treatment. It is suggested that the test might be used on cerebro-spinal fluid in cerebral malaria to determine the degree of activity of the infection and that it might be used as a routine on prospective blood donors. Ninety persons in whom there was no evidence of either malaria or liver disease were also examined in all the cephalin flocculation test was negative. Norman White

JENNINGS G H. Coma as Onset in a Case of Malaria in England. [Memoranda.] *Brit Med J* 1946 Apr 27 650

The patient, a man aged 23 had lived in West Africa for 11 months during which he had taken 10 grains of quinine daily as a prophylactic (presumably effective) against malaria, but had discontinued taking it on leaving for England. A few days after his arrival in England he had had two very short attacks of fever and felt apathetic and rather sleepy during the following six weeks for a week before his admission to hospital he had been treated at his home for anaemia. He complained of pain in his right arm 24 hours before admission and on the evening of the next day coma with high fever (105°F) developed suddenly and he was admitted to hospital.

Condition on admission.—Temperature 104.2°F respiration 36 deep and noisy pupils moderately dilated not reacting to light no neck rigidity tendon jerks much exaggerated bilateral ankle clonus present plantar reflexes extensor abdominal reflexes absent spleen 3 inches below the ribs blood showed numerous subtertian malarial parasites.

Course and treatment.—He was given quinine bishydrochloride 20 grains intravenously and, later tepid sponging his temperature fell and he quickly recovered consciousness. Next day he was bright and alert but very pale the spleen was undiminished in size the blood showed Hb 40 per cent. R.B.C. 1 720 000 C.I. 1 17 W.B.C. 3 260 (P 5 per cent., L 40 per cent. M. 8 per cent.) He was given quinine bishydrochloride 10 grains t.i.d. and mepacrine 0.1 gm. t.i.d. for two days then quinine bishydrochloride 5 grains t.i.d. and ferri et ammon. cit. 40-90 grains daily. Six days after admission the spleen was no longer palpable and the abdominal reflexes were normal but the tendon jerks in the legs were still slightly exaggerated. After taking a 5-day course of pamaquin 0.02 gm. t.i.d. he was discharged on the 17th day after admission his blood then showed Hb. 70 per cent. R.B.C. 3 860 000 C.I.O. 92 W.B.C. 6 400 (P 72 per cent. L 20 per cent. M. 7 per cent. E 1 per cent.) His temperature became normal after the second day. Two months later he showed no anaemia and had had no relapses.

PARRY E. **Surgery in Malaria.** *Lancet* 1946 Jan 12, 49-51

In many cases of *P. falciparum* infection there is a tendency to haemorrhage. Such haemorrhage can lead to mistakes in diagnosis. It was the outstanding characteristic of eight interesting surgical cases cited by the author in all of which the prompt recognition of a coexisting *P. falciparum* infection and the prompt intravenous administration of quinine were quickly followed by cessation of bleeding. The cases include a compound fracture of both bones of the leg a penetrating wound of the neck a fracture of the pelvis with rupture of the urethra profuse epistaxis two cases of haemorrhage into adenomata of the thyroid and a case of appendicitis in which numerous subserous petechial haemorrhages in visceral and parietal peritoneum were attributable to malaria infection. Malaria is liable to concentrate on the lungs after an inhalation anaesthesia just as it tends to cause cerebral malaria after intravenous anaesthesia.

The author states that to anyone who has been in the far-eastern theatre of war since its beginning the beneficial changes wrought by mepacrine in the treatment of malaria are little short of miraculous.

DOLE, V. P. & EMERSON, K. Jr with the technical assistance of Esther BRAUN
Electrophoretic Changes in the Plasma Protein Patterns of Patients with Relapsing Malaria. *J. Clin. Investigation* 1945 Sept v 24 No. 5 644-7
1 fig

The total protein, albumin and globulin content of the plasma of eight patients suffering from *P. vivax* malaria was measured during the clinical attack after the patients had been allowed three paroxysms, and at varying times subsequently. The albumin and globulin fractions were estimated by electrophoresis and by salt fractionation.

The authors found that during the malarial attack the total protein remained within normal limits. The albumin/globulin ratio was depressed. The increase in globulin occurred mainly in the fibrinogen and γ globulin fractions. The mobility of the protein was normal during the malarial attack. The plasma protein content returned to normal after specific treatment and during the inter-relapse period.

In a single case of *P. falciparum* malaria which was untreated for 3 weeks, the total protein dropped to 3.64 gm. per cent. (normal value 6.7) with an albumin globulin ratio of 1.3 (salt fractionation) or 0.72 (electrophoretic).—

The author considers that the changes in plasma protein are not specific in malaria. Consequently methods of diagnosis based on the protein pattern are not reliable in malaria [see PROSKE & WATSON, this *Bulletin* 1939 v 36 813] particularly as the pattern returns to normal between relapses although the infection with *P. vivax* must persist during this period.

[The authors do not attempt to relate the protein pattern to the effects of treatment although their figures show that in one case treated with atabrine (mepacrine) the plasma protein reached a maximum concentration during treatment whereas in another case treated with quinine the protein was depressed during treatment and rose to a maximum after treatment was finished]

YUDEKIN J. Urinary Mepacrine in relation to Incidence and Diagnosis of Malaria. *Lancet* 1946 Mar 16 377-80 1 chart

This paper describes the results of estimation of urinary mepacrine in groups of healthy European Service personnel in W. Africa with different malarial incidence (all malignant tertian) and in unselected patients admitted to hospital there. All the subjects were supposed to be having 0.7 gm. of mepacrine weekly as a suppressive. For estimation the method of YUDEKIN [this *Bulletin* 1945 v 42 863] was employed. Since there is a relationship between the amount of mepacrine excreted in the urine and its level in the blood, the amount of drug excreted in unit time might therefore be related to the incidence of malaria. As completely reliable 24-hour specimens of urine could not be obtained 8-hour specimens were used. It was found that the lowest excretion of drug occurred in the group of subjects with highest incidence of malaria. For practical reasons a method was developed in which random samples of urine were used for the estimation of mepacrine excretion. Output depends on concentration of drug as well as on the volume of urine passed, and the latter has an influence on the specific gravity of the sample. To estimate the output of mepacrine, its concentration in a random sample of urine was determined and also the specific gravity of the specimen. The concentration value for a urine of sp. gr. 1.010 was then calculated and the author terms this latter value—the standard urinary concentration of mepacrine. It was found that figures for the relative excretion of mepacrine in individuals or in groups were similar when estimated either as standard concentration or as total output over a period. The concentration of mepacrine was measured by the former method in 149 cases divided into four groups as follows—(1) proved malaria (2) clinical malaria (no parasites seen in blood but signs and symptoms suggestive) (3) other medical conditions (4) surgical conditions. In cases of proved malaria the excretion of mepacrine was found to be low. The author believes that a high excretion of mepacrine should exclude a diagnosis of malaria. From his own and other evidence he concludes that a

high proportion of cases diagnosed as clinical malaria are in fact not malaria. [This is in contrast to the experience of HYMAN (this Bulletin 1945 v 42, 987) in South Pacific Areas.]

J. D. FALLON

ELLERBROOK, L. D. LIPPINCOTT, S. W. CATEXO, C. F. GORDON, H. H. & MARBLE, A. Plasma Quinacrine Concentration in Treatment of *Plasmodium vivax* Malaria acquired in the South Pacific. *Arch Intern. Med.* 1945 Nov-Dec. v 78 No 5 352-7 7 figs.

Mepacrine (quinacrine) was estimated by the method of BRODIE and UDENFRIEND [this Bulletin 1943 v 40 821]. When known amounts were added to plasma, an average recovery of 96 per cent. (82-110 per cent.) was obtained. An average blank value of 3 micrograms per litre was observed in the plasma of untreated persons. Determinations were made on 6733 specimens from 291 patients with relapsing malaria, treated in Texas. Doses were given with meals (at 7.30 a.m., 11.30 a.m. and 5 p.m.) and specimens for estimation were collected before breakfast. There were four groups of patients. Group I (54 patients) received 0.2 gm. orally at meals and at midnight for 5 doses and then 0.1 gm. thrice daily until a total of 2.8 gm. had been received. The plasma concentration in this group is shown in Fig. 1 in which the heavy line represents the average for the group and the two lighter lines indicate 1 standard deviation on each side of the mean (and include approximately 2/3 of all values). Patients in Group II received 2.8 gm. of mepacrine on 8 Group I. Then they were given a rest for 24 hours, and 0.1 gm. of mepacrine on 8 naphthoate thrice daily for 3 days, followed by 0.1 gm. of mepacrine on 8 days of the week until the sixteenth day from the start of treatment. Group III was similar but the pamaquin was omitted. The plasma levels in these two groups were similar to those of Group I except that after the 14th day an approximately steady level of plasma mepacrine was maintained at 20-30 micrograms per litre. The average diurnal variation is shown in Fig. 2. In Group IV 0.4 gm. of mepacrine was given at 9 a.m. followed by 0.2 gm. at 4.30 p.m. and at 1 a.m. then 0.2 gm. was given at 9 a.m. and 9 p.m. for 6

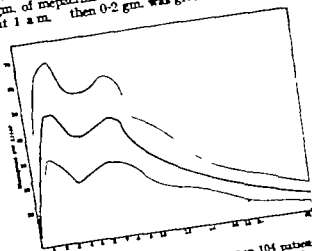

Fig. 1.—Fasting plasma quinacrine concentrations in 104 patients for eight days and in 54 patients thereafter (2.8 Gm. of quinacrine hydrochloride in one week). The heavy line indicates average values. In Figs. 1 and 4 fine lines indicate 1 standard deviation (includes approximately two-thirds of all values).

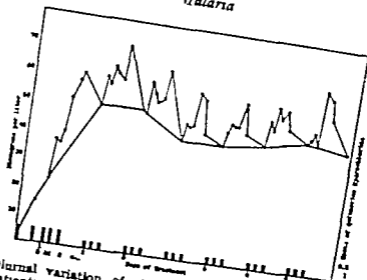

Fig 2—Diurnal variation of plasma quinacrine concentrations in 104 patients given 28 Gm of quinacrine hydrochloride

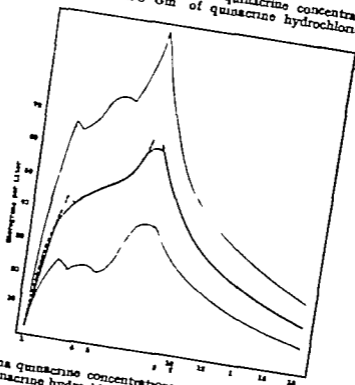

Fig 4—Plasma quinacrine concentrations of 35 patients who were given 32 Gm of quinacrine hydrochloride in one week. The heavy line indicates average fasting values. The broken line indicates five hours after administration of 0.2 Gm.

days. The average plasma concentration of mepacrine is shown in Fig 4. Under these treatments pyrexia and other symptoms rapidly subsided and parasites disappeared from the blood.

ABBEY E. A. & LAWRENCE E. A. The Effect of Atabrine Suppressive Therapy on Eyesight in Pilots. *J Amer Med Ass* 1946 Mar 23; 130 No. 12, 786-7

1 The continued use of atabrine in doses of one tablet (0.1 Gm.) a day appears to have no effect on visual acuity except in a highly sensitive and rare individual.

to be related to natural and acquired immunity which would be modified by the destruction of lymphocytes which irradiation brings about.
